FOURTH EDITION
TIETZ Textbook of
CLINICAL CHEMISTRY
AND MOLECULAR
DIAGNOSTICS
Edited by
Carl A. Burtis
Edward R. Ashwood
David E. Bruns

TIETZ *Textbook of*
Clinical Chemistry AND Molecular Diagnostics

CARL A. BURTIS, Ph.D.
Senior Technical Specialist
Health Services Division
Oak Ridge National Laboratory
Oak Ridge, Tennessee;
Clinical Professor of Pathology
University of Utah School of Medicine
Salt Lake City, Utah

EDWARD R. ASHWOOD, M.D.
Professor of Pathology
University of Utah School of Medicine,
Chief Medical Officer/Laboratory Director
ARUP Laboratories
Salt Lake City, Utah

DAVID E. BRUNS, M.D.
Professor of Pathology
University of Virginia Medical School,
Director of Clinical Chemistry and Associate Director of Molecular Diagnostics
University of Virginia Health System
Charlottesville, Virginia;
Editor, *Clinical Chemistry*
Washington, D.C.

FOURTH EDITION

with **944** *illustrations and* **12** *color plates*

ELSEVIER
SAUNDERS

To
Marvel, Candice, and **Liz,**
our friends and companions in life,
for their understanding, encouragement, and patience,
especially during our many absences—the mental as well as the physical.

And to the memory of **David J. Newman,**
a good friend and valued colleague.

Contributors

CONSTANTIN ALIFERIS, M.D., Ph.D.
Assistant Professor of Biomedical Informatics,
Director, Discovery Systems Laboratory
Department of Biomedical Informatics
Vanderbilt University School of Medicine
Nashville, Tennessee
Clinical Evaluation of Methods

THOMAS ANNESLEY, Ph.D.
Professor of Clinical Chemistry
University of Michigan Medical School
Ann Arbor, Michigan
Mass Spectrometry

FRED S. APPLE, Ph.D.
Medical Director, Clinical Laboratories
Hennepin County Medical Center,
Professor of Laboratory Medicine & Pathology
University of Minnesota School of Medicine
Minneapolis, Minnesota
Cardiac Function

DOMINIK ARONSKY, M.D., Ph.D.
Department of Biomedical Informatics
Vanderbilt University Medical Center
Assistant Professor of Biomedical Informatics & Emergency Medicine
Vanderbilt University
Nashville, Tennessee
Clinical Evaluation of Methods

EDWARD R. ASHWOOD, M.D.
Professor of Pathology
University of Utah School of Medicine,
Chief Medical Officer/Laboratory Director
ARUP Laboratories
Salt Lake City, Utah
Clinical Chemistry of Pregnancy; Clinical Chemistry of Pregnancy Appendix

MALCOLM BAINES, F.R.S.C., F.R.C.Path.
Principal Clinical Scientist
Royal Liverpool University Hospital
Liverpool, United Kingdom
Vitamins and Trace Elements; Vitamins and Trace Elements Appendix

RENZE BAIS, Ph.D.
Principal Hospital Scientist
Department of Clinical Biochemistry
Pacific Laboratory Medicine Services
Royal North Shore Hospital
Senior Clinical Associate
Department of Medicine
University of Sydney
Sydney, NSW, Australia
Principles of Clinical Enzymology; Enzymes; Enzymes Appendix

EDWARD W. BERMES, Jr., Ph.D.
Professor Emeritus, Department of Pathology
Loyola University Medical Center
Maywood, Illinois
Introduction to Principles of Laboratory Analyses and Safety; Introduction to Principles of Laboratory Analyses and Safety Appendix; Specimen Collection and Processing; Preanalytical Variables and Biological Variation

ERNEST BEUTLER, M.D.
Chairman, Department of Molecular and Experimental Medicine
The Scripps Research Institute
La Jolla, California
Hemoglobin, Iron, and Bilirubin; Hemoglobin, Iron, and Bilirubin Appendix

RONALD A. BOOTH, Ph.D.
Assistant Professor, University of Ottawa,
Clinical Biochemist, The Ottawa Hospital
Ottawa, Ontario, Canada
Tumor Markers

PATRICK M.M. BOSSUYT, Ph.D.
Head, Department Clinical Epidemiology and Biostatistics,
Professor of Clinical Epidemiology
Academic Medical Center
University of Amsterdam
Amsterdam, The Netherlands
Introduction to Laboratory Medicine and Evidence-Based Laboratory Medicine; Introduction to Laboratory Medicine and Evidence-Based Laboratory Medicine Appendix

JAMES C. BOYD, M.D.
Department of Pathology
University of Virginia Medical Center
Charlottesville, Virginia
Automation in the Clinical Laboratory; Automation in the Clinical Laboratory Appendix; Selection and Analytical Evaluation of Methods—With Statistical Techniques; Selection and Analytical Evaluation of Methods—With Statistical Techniques Appendix

DAVID E. BRUNS, M.D.
Professor of Pathology
University of Virginia Medical School,
Director of Clinical Chemistry and Associate Director of Molecular Diagnostics
University of Virginia Health System
Charlottesville, Virginia;
Editor, *Clinical Chemistry*
Washington, D.C.
Introduction to Laboratory Medicine and Evidence-Based Laboratory Medicine; Introduction to Laboratory Medicine and Evidence-Based Laboratory Medicine Appendix; Reference Information for the Clinical Laboratory

BONNY LEWIS BUKAVECKAS, Ph.D.
Assistant Professor, Department of Pharmacy
Virginia Commonwealth University
Richmond, Virginia
Pharmacogenetics

MARY F. BURRITT, Ph.D.
Director, Metals Laboratory
Medical Co-Director, Central Clinical Laboratory
Mayo Clinic,
Professor of Laboratory Medicine
Associate Dean, Mayo School of Health Sciences
Mayo Clinic College of Medicine
Rochester, Minnesota
Toxic Metals; Toxic Metals Appendix

CARL A. BURTIS, Ph.D.
Senior Technical Specialist
Health Services Division
Oak Ridge National Laboratory
Oak Ridge, Tennessee;
Clinical Professor of Pathology
University of Utah School of Medicine
Salt Lake City, Utah
Chromatography; Reference Information for the Clinical Laboratory

JOHN BUTZ, B.A.
Supervisor, Metals Laboratory
Department of Laboratory Medicine and Pathology
Mayo Clinic
Rochester, Minnesota
Toxic Metals; Toxic Metals Appendix

ANGELA M. CALIENDO, M.D., Ph.D.
Associate Professor of Pathology and Laboratory Medicine
Emory University School of Medicine,
Vice Chair, Clinical Pathology
Emory University Hospital
Atlanta, Georgia
Molecular Methods in Diagnosis and Monitoring of Infectious Diseases

DANIEL W. CHAN, Ph.D., D.A.B.C.C., F.A.C.B.
Professor of Pathology, Oncology, Radiology, and Urology
Johns Hopkins University School of Medicine,
Director, Clinical Chemistry Division
Johns Hopkins Hospital
Baltimore, Maryland
Tumor Markers

ROSSA W.K. CHIU, M.B.B.S., Ph.D., F.R.C.P.A.
Associate Professor
Department of Chemical Pathology
The Chinese University of Hong Kong
Hong Kong SAR
Principles of Molecular Biology and Approaches to Nucleic Acid Isolation

ALLAN C. DEACON, B.Sc., Ph.D., Dip.C.B., F.R.C.Path.
Consultant Clinical Scientist
King's College Hospital
Denmant Hill, London, England
Porphyrins and Disorders of Porphyrin Metabolism; Porphyrins and Disorders of Porphyrin Metabolism Appendix

MICHAEL P. DELANEY, B.Sc., M.D., M.R.C.P.
Consultant Nephrologist
Renal Unit, Kent & Canterbury Hospital
East Kent Hospitals NHS Trust
Canterbury, Kent, United Kingdom
Kidney Disease

LAURENCE M. DEMERS, Ph.D., F.A.C.B., D.A.B.C.C.
Director, Clinical Chemistry, Core Endocrine Laboratory, GCRC Core Laboratory
M.S. Hershey Medical Center
Distinguished Professor of Pathology and Medicine
Penn State University College of Medicine
Hershey, Pennsylvania
Pituitary Function; The Adrenal Cortex; The Thyroid: Pathophysiology and Thyroid Function Testing

ELEFTHERIOS P. DIAMANDIS, M.D., Ph.D.
Professor and Head, Division of Clinical Biochemistry
University of Toronto,
Section Head of Clinical Biochemistry
Mount Sinai Hospital
Toronto, Ontario, Canada
Tumor Markers

PAUL D'ORAZIO, Ph.D.
Director, Sensor Development
Instrumentation Laboratory
Lexington, Massachusetts
Electrochemistry and Chemical Sensors

BASIL T. DOUMAS, Ph.D.
Professor Emeritus
Department of Pathology
Medical College of Wisconsin
Milwaukee, Wisconsin
Hemoglobin, Iron, and Bilirubin; Hemoglobin, Iron, and Bilirubin Appendix

D. ROBERT DUFOUR, M.D.
Chief, Pathology and Laboratory Medicine Service (retired)
Veterans Affairs Medical Center, Washington DC,
Professor of Pathology
George Washington University Medical Center
Washington DC;
Adjunct Professor of Pathology
Uniformed Services University of the Health Sciences
Bethesda, Maryland
Liver Disease

GRAEME EISENHOFER, Ph.D.
Staff Scientist, Clinical Neurocardiology Section
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, Maryland
Catecholamines and Serotonin; Catecholamines and Serotonin Appendix

GEORGE H. ELDER, M.D.
Emeritus Professor
Department of Medical Biochemistry and Immunology
Unversity of Wales College of Medicine
Cardiff, United Kingdom
Porphyrins and Disorders of Porphyrin Metabolism; Porphyrins and Disorders of Porphyrin Metabolism Appendix

KOJO S.J. ELENITOBA-JOHNSON, M.D.
Associate Professor of Pathology
University of Utah School of Medicine,
Director, Molecular Pathology Fellowship Training Program
Director, Molecular Hematopathology and Proteomics
ARUP Laboratories
Salt Lake City, Utah
Molecular Genetics and Diagnosis of Hematopoietic Neoplasms

DAVID B. ENDRES, Ph.D.
Professor of Clinical Pathology
Keck School of Medicine
University of Southern California,
Consultant, Chemistry
Los Angeles County University of Southern California Medical Center
Los Angeles, California
Mineral and Bone Metabolism

GORDON S. FELL, Ph.D., F.R.C.Path.
Emeritus Professor of Pathological Biochemistry
University of Glasgow
Glasgow, Scotland
Vitamins and Trace Elements; Vitamins and Trace Elements Appendix

ANDREA FERREIRA-GONZALEZ, Ph.D.
Associate Professor of Pathology
Virginia Commonwealth University,
Director, Molecular Diagnostics Laboratory
Medical College of Virginia Hospitals
Richmond, Virginia
Molecular Methods in Diagnosis and Monitoring of Infectious Diseases

ELIZABETH L. FRANK, Ph.D., D.A.B.C.C., F.A.C.B.
Assistant Professor (Clinical)
Department of Pathology
University of Utah Health Sciences Center,
Medical Director, Analytic Biochemistry
ARUP Laboratories
Salt Lake City, Utah
Catecholamines and Serotonin Appendix

ANN M. GRONOWSKI, Ph.D.
Assistant Professor
Washington University School of Medicine,
Assistant Medical Director, Chemistry
Barnes-Jewish Hospital
St. Louis, Missouri
Reproductive Related Disorders

SIHOUN HAHN, M.D., Ph.D.
Co-director, Biochemical Genetics Laboratory,
Associate Professor of Laboratory Medicine and Pathology
Mayo Clinic College of Medicine
Rochester, Minnesota
Inborn Errors of Amino Acid, Organic Acid, and Fatty Acid Metabolism; Inborn Errors of Amino Acid, Organic Acid, and Fatty Acid Metabolism Appendix

DORIS M. HAVERSTICK, Ph.D.
Associate Professor
University of Virginia, Department of Pathology
Charlottesville, Virginia
Specimen Collection and Processing

CHARLES D. HAWKER, Ph.D., M.B.A., F.A.C.B.
Associate Professor of Pathology (Adjunct)
University of Utah School of Medicine,
Scientific Director, Automation and Special Projects
ARUP Laboratories
Salt Lake City, Utah
Automation in the Clinical Laboratory; Automation in the Clinical Laboratory Appendix

SHANNON HAYMOND, Ph.D.
Department of Pathology
Washington University School of Medicine
St. Louis, Missouri
Reproductive Related Disorders

TREFOR HIGGINS, M.Sc.
Associate Clinical Professor
University of Alberta,
Co-Director of Clinical Chemistry
Dynacare Kasper Medical Laboratory
Edmonton, Alberta, Canada
Hemoglobin, Iron, and Bilirubin; Hemoglobin, Iron, and Bilirubin Appendix

PETER G. HILL, Ph.D., C. Chem., F.R.S.C., F.R.C.Path.
Consultant Clinical Scientist
Department of Clinical Pathology
Derby Hospitals NHS Foundation Trust
Derby, United Kingdom
Gastric, Pancreatic, and Intestinal Function

ALLAN S. JAFFE, M.D.
Consultant in Cardiology/Internal Medicine and Laboratory Medicine and Pathology
Professor of Medicine
Mayo Clinic and Mayo Medical School
Rochester, Minnesota
Cardiac Function

A. MYRON JOHNSON, M.D.
Clinical Professor of Obstetrics and Gynecology
University of North Carolina
Chapel Hill, North Carolina
Amino Acids, Peptides, and Proteins

STEPHEN E. KAHN, Ph.D.
Professor
Pathology, Cell Biology, Neurobiology and Anatomy
Vice Chair
Laboratory Medicine Director
Core Laboratory Operations Section Chief and Director
Clinical Chemistry, Toxicology and Near Patient Testing
Loyola University Medical Center
Maywood, Illinois
Introduction to Principles of Laboratory Analyses and Safety; Introduction to Principles of Laboratory Analyses and Safety Appendix

MALEK KAMOUN, M.D., Ph.D.
Professor of Pathology and Laboratory Medicine
University of Pennsylvania School of Medicine,
Director, Clinical Immunology Lab
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Identity Assessment

RAYMOND KARCHER, Ph.D.
Clinical Chemist, William Beaumont Hospital
Royal Oak, Michigan,
Adjunct Associate Professor
Oakland University
Rochester, Michigan
Electrophoresis

ANTHONY A. KILLEEN, M.D., Ph.D.
Director of Clinical Laboratories
Fairview-University Medical Center,
Associate Professor
Department of Laboratory Medicine and Pathology
University of Minnesota
Minneapolis, Minnesota
Design and Operation of the Molecular Diagnostics Laboratory

GEORGE G. KLEE, M.D., Ph.D.
Chair, Division of Experimental Pathology
Department of Laboratory Medicine and Pathology,
Professor of Laboratory Medicine
Mayo Clinic College of Medicine
Rochester, Minnesota
Quality Management

MICHAEL KLEEREKOPER, M.D., F.A.C.E., F.A.C.B.
Professor of Medicine and Pathology
Wayne State University School of Medicine

Foreword

During the last 10 years, new results of biomedical research and new developments in biotechnology entered the medical sciences and changed traditional orientations. The identification of human genes and the cellular functions of gene products resulted in new concepts in the explanation of several diseases, especially in malignant transformation and cancer. Developments in communication technology with fast information exchange between researchers and clinicians globally led to fundamental changes in several medical disciplines and integration of new knowledge into the practice of medicine. The surgeon using endoscopic procedures, the radiologist employing magnetic resonance in metabolism investigations, and the anatomic pathologist applying molecular biology and immunohistochemistry staining in diagnostics are a few examples of these rapid changes. This is also true for clinical chemistry and laboratory medicine, whose objectives now extend beyond diagnosis and monitoring to include risk assessment and prevention. For clinicians and laboratorians, it is pertinent in a time of "managed patient care" to decide as a team on the most efficient diagnostic strategy for a patient that combines clinical information with laboratory results.

The fourth edition of the famous *Tietz Textbook* recognizes new areas requiring greater recognition and understanding from clinical chemists as they strive to be laboratory medicine consultants, linking science and medicine for the benefit of patients and the health of the community. The most immediate change is in the name, which has been enlarged to the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*. The importance of this change is highlighted by the introduction of a section dedicated to molecular diagnostics and genetics. Understanding the principles of molecular biology in hematology, infectious disease, and genetics, together with the rapidly expanding area of pharmacogenetics, clearly emphasizes how the clinical laboratory must link technology and clinical understanding and then translate the results of such investigations into terms understandable by clinicians and patients.

It is a notable achievement for any book to become an internationally recognized reference work that successfully appeals to professionals from different medical disciplines and cultures while still managing to overcome the barriers that are raised by language differences. All over the world the *Tietz Textbook of Clinical Chemistry* has been acknowledged as an outstanding, broadly based source of knowledge and information for our profession. It provides guidance for the youngest to the oldest, whether neophyte or laboratory-tested veteran, thus bridging generation gaps. It is a tool not only for the education of those training to be clinical laboratory professionals but for the continuing education of those who may have acquired specific expertise and recognition, yet who need to keep current with an extensive understanding of our present and future scientific, technological, and organizational development.

Such recognition for a reference book is not easily attained or maintained and requires considerable talent and effort to have its reputation enhanced. This fourth edition once again faces up to the challenge of freshness and relevance in what to introduce and what to leave out. The judicious selection of subjects and authors, together with their integration into an up-to-date, coherent, and balanced text, is the responsibility of the editors. Following the excellent first edition, which reflected the science and personality of Dr. Norbert Tietz, the second and third editions were edited by Dr. Carl A. Burtis and Dr. Edward R. Ashwood. The fourth edition benefits once again from their experience, complementary skills, and knowledge of science and technology as applied to clinical chemistry and laboratory medicine. Dr. David E.

Bruns, widely known and respected as the Editor of *Clinical Chemistry,* is the new addition to the editorial group. Making a strong editorial team even stronger is a far-sighted move that inspires confidence.

This edition is notable also for the large number of new authors and the challenge given to them to respond to significant regroupings of chapters and subjects, thus introducing room for new information and discussion of new topics. The principles of evidence-based laboratory medicine are addressed. The basic science, its application and management in the clinical laboratory, allied with the interpretation and use of the information produced, are all components of the evidence base. This new edition reflects the continuing maturity of an excellent textbook that will be an extremely useful aid for clinicians and laboratory professionals in their daily work.

Professor Matthew McQueen

Kaiser Franz Josef Hospital
Vienna, Austria

Preface

The goal of the editors of the prior three editions of the *Tietz Textbook of Clinical Chemistry* (1986, 1994, 1999) was to produce an authoritative textbook that provided a current and comprehensive overview of the discipline of clinical chemistry. We have set the same goal for this fourth edition. Meeting this goal has become a greater challenge with each edition as technical and medical advances expand the discipline in both depth and breadth and blur the traditional boundaries between clinical chemistry and other disciplines of laboratory medicine.

To meet this challenge and yet keep the book manageable and in one volume has necessitated extensive revision of the format of the fourth edition and additions to its content. The first major change was to add eight new chapters on molecular diagnostics, a change reflected in amending the title of the fourth edition to the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics.* A second major change was the addition of Professor David E. Bruns as a co-editor to our editorial team. The two editors of the previous edition found that his wealth of knowledge and experience and his superb editing skills were invaluable in producing this new edition.

As a result of adding new chapters and the retirement of several authors who had participated in earlier editions, many new authors have joined our team of core veterans from previous editions. In fact, 66 of the 97 authors represented in the fourth edition are new to the effort. These knowledgeable and enthusiastic new authors coupled with core veterans have produced chapters that are timely and reflect the state-of-the-art in their respective fields. The international flavor of the book and the international nature of the field are more evident than ever before in the list of countries represented by this outstanding group of colleagues.

In addition to the eight new chapters on molecular diagnostics (Chapters 36-43), other new chapters include those on Nanotechnology and Microfabrication (Chapter 10), Point-of-Care Testing (Chapter 12), Introduction to Laboratory Medicine and Evidence-Based Laboratory Medicine (Chapter 13), and Inborn Errors of Amino Acid, Organic Acid, and Fatty Acid Metabolism (Chapter 55). We have also removed a few chapters and combined elements from them into new chapters including Selection and Analytical Evaluation of Methods—With Statistical Techniques (Chapter 14), Vitamins and Trace Elements (Chapter 30), and Hemoglobin, Iron, and Bilirubin (Chapter 31). The fourth edition now contains 56 chapters, a large increase when compared with the 20 chapters of the first edition. These 56 chapters include over 10,000 references, 900 figures, and 500 tables and boxes. We have grouped these chapters into seven sections entitled Laboratory Principles, Analytical Techniques and Instrumentation, Principles of Laboratory Medicine, Analytes, Molecular Diagnostics and Genetics, Pathophysiology, and Reference Information. As in previous editions, the reader will find that the distinction between "Analytes" and "Pathophysiology" is indistinct as several analytes are discussed in the chapters included in the Pathophysiology section and the pathophysiologies of several disorders are discussed in chapters placed in the Analytes section.

A major addition to the fourth edition is a companion website (http://evolve.elsevier.com/Tietz/textbook/), which contains analytical methods, case studies, and supplementary information. We plan to periodically include updated and new information on this website, including corrections when errors are found in the textbook. We invite readers to call such errors to our attention so that corrections can be made and subsequent printings of the textbook will reflect the process of continuous improvement for which we strive. All of the reference citations in the book are also listed in the Evolve website where they

are linked electronically to the PubMed database of articles and abstracts. Because PubMed has links to on-line journals, readers can access the full texts of many cited articles with two clicks of a mouse.

Information technology played a much-increased role in the preparation and production of the fourth edition. Each chapter was submitted, edited, and typeset electronically. As with the third edition of the *Textbook*, many of the figures, especially those that included chemical structure were drawn or revised by one of us (EA) using ChemWindows software (http://www.softshell.com). This resulted in a uniform representation of chemical structures and facilitated the integration of figures with the text while reducing errors. The Internet also helped authors and editors to find the latest information and sources of products. Readers will note that references to web-based sources of information are found throughout the text.

We greatly appreciate the opportunity provided to us by Elsevier to participate in the preparation of the fourth edition of this textbook. It has been an exciting, challenging, and educational experience. We have endeavored to ensure that this edition will live up to the reputation and success of its distinguished predecessors. We have enjoyed working with the team of dedicated authors who have spent countless hours preparing comprehensive chapters that are authoritative and timely. We believe that they have produced a textbook that is reflective of the diverse, technical, and practical nature of the current practice of clinical laboratory science and medicine.

We have also benefited from and enjoyed working with the Elsevier staff, especially Managing Editor, Mindy Hutchinson; Developmental Editor, Ellen Wurm; and Senior Project Manager, Rachel Dowell. Their patience, warm cooperation, sound advice, and professional dedication are gratefully acknowledged.

David E. Bruns

Contents

Color insert follows page 1468.

SECTION I
LABORATORY PRINCIPLES

1 Introduction to Principles of Laboratory Analyses and Safety, 3
Edward W. Bermes, Jr., Ph.D., Stephen E. Kahn, Ph.D., and Donald S. Young, M.B., Ph.D.

CONCEPT OF SOLUTE AND SOLVENT, 3
Definitions, 3
Expressing Concentrations of Solutions, 3
UNITS OF MEASUREMENT, 5
International System of Units, 5
Decimal Multiples and Submultiples of SI Units, 6
Applications of SI in Laboratory Medicine, 6
Problem Areas in the Use of SI Units, 8
Conversion Rules, 9
Standardized Reporting of Test Results, 9
CHEMICALS AND REFERENCE MATERIALS, 10
Reagent Grade Water, 10
Reagent Grade or Analytical Reagent Grade (AR) Chemicals, 12
Ultrapure Reagents, 12
Reference Materials, 12
BASIC TECHNIQUES AND PROCEDURES, 12
Volumetric Sampling and Dispensing, 12
Centrifugation, 19
Measurement of Radioactivity, 21
Gravimetry, 23
Thermometry, 25
Buffer Solutions, 25
Procedures for Processing Solutions, 26
SAFETY, 27
Safety Program, 28
Safety Equipment, 28
Safety Inspections, 28
Mandated Plans, 29
Ergonomics Program, 30
Hazards in the Laboratory, 30

2 Specimen Collection and Processing, 41
Donald S. Young, M.B., Ph.D., Edward W. Bermes, Jr., Ph.D., and Doris M. Haverstick, Ph.D.

SPECIMEN COLLECTION, 41
Blood, 41
Urine, 49
Feces, 52
Spinal Fluid, 52
Synovial Fluid, 52
Amniotic Fluid (Amniocentesis), 53
Pleural, Pericardial, and Ascitic Fluids, 53
Saliva, 53
Swabs, 53
Solid Tissue, 53
Hair and Finger Nails, 54
HANDLING OF SPECIMENS FOR TESTING, 54
Maintenance of Specimen Identification, 54
Preservation of Specimens in Transit, 54
Separation and Storage of Specimens, 56
Transport of Specimens, 56

SECTION II
ANALYTICAL TECHNIQUES AND INSTRUMENTATION

3 Optical Techniques, 61
L.J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path.

NATURE OF LIGHT, 61
SPECTROPHOTOMETRY, 62
Basic Concepts, 62
Instrumentation, 64
REFLECTANCE PHOTOMETRY, 72
FLAME EMISSION SPECTROPHOTOMETRY, 73
ATOMIC ABSORPTION SPECTROPHOTOMETRY, 73
Basic Concepts, 73
Instrumentation, 73
Interferences in Atomic Absorption Spectrophotometry, 74
FLUOROMETRY, 75
Basic Concepts, 75

Instrumentation, 77
Limitations of Fluorescence Measurements, 83
PHOSPHORESCENCE, 84
CHEMILUMINESCENCE, BIOLUMINESCENCE, AND ELECTROCHEMILUMINESCENCE, 84
Basic Concepts, 84
Instrumentation, 85
Limitations of Chemiluminescence and Electrochemiluminescence Measurements, 85
NEPHELOMETRY AND TURBIDIMETRY, 85
Basic Concepts, 85
Measurement of Scattered Light, 87
Instrumentation, 88
Limitations of Light-Scattering Measurements, 88

4 **Electrochemistry and Chemical Sensors**, 93
Paul D'Orazio, Ph.D., and Mark E. Meyerhoff, Ph.D.

POTENTIOMETRY AND ION-SELECTIVE ELECTRODES, 93
Basic Concepts, 93
Types of Electrodes, 94
Direct Potentiometry by ISE—Units of Measure and Reporting for Clinical Applications, 100
VOLTAMMETRY/AMPEROMETRY, 101
Basic Concepts, 101
Applications, 103
CONDUCTOMETRY, 105
COULOMETRY, 106
OPTICAL CHEMICAL SENSORS, 106
Basic Concepts, 107
Applications, 107
BIOSENSORS, 108
Enzyme-Based Biosensors With Amperometric Detection, 108
Enzyme-Based Biosensors With Potentiometric and Conductometric Detection, 110
Enzyme-Based Biosensors With Optical Detection, 111
Affinity Sensors, 112
IN VIVO AND MINIMALLY INVASIVE SENSORS, 113

5 **Electrophoresis**, 121
Raymond Karcher, Ph.D., and James P. Landers, Ph.D.

BASIC CONCEPTS AND DEFINITIONS, 121
THEORY OF ELECTROPHORESIS, 121
CONVENTIONAL ELECTROPHORESIS, 122
Instrumentation, 122
General Operations, 125
Technical and Practical Considerations, 126
Types of Electrophoresis, 128
CAPILLARY ELECTROPHORESIS, 130
Instrumentation, 131
Technical Considerations, 133
Modes of Operation, 134
MICROCHIP ELECTROPHORESIS, 135
Instrumentation, 135
Fabrication of Microchips, 136
Molecular Diagnostics Using Microchips, 137

6 **Chromatography**, 141
M. David Ullman, Ph.D., and Carl A. Burtis, Ph.D.

BASIC CONCEPTS, 141
SEPARATION MECHANISMS, 142
Ion-Exchange Chromatography, 142
Partition Chromatography, 143
Adsorption Chromatography, 144
Affinity Chromatography, 144
Size-Exclusion Chromatography, 144
RESOLUTION, 145
Retention Factor (k′), 146
Efficiency (N), 147
PLANAR CHROMATOGRAPHY, 148
COLUMN CHROMATOGRAPHY, 149
Gas Chromatography, 149
Liquid Chromatography, 155
QUALITATIVE AND QUANTITATIVE ANALYSES, 161
Analyte Identification, 161
Analyte Quantification, 161

7 **Mass Spectrometry**, 165
Thomas Annesley, Ph.D., Alan L. Rockwood, Ph.D., and Nicholas E. Sherman, Ph.D.

BASIC CONCEPTS AND DEFINITIONS, 165
INSTRUMENTATION, 167
Ion Source, 167
Vacuum System, 171
Mass Analyzers, Ion Detectors, and Tandem Mass Spectrometers, 171
Detectors, 180
Computer and Software, 181
CLINICAL APPLICATIONS, 181
Gas Chromatography-Mass Spectrometry, 182
Liquid Chromatography-Mass Spectrometry, 182
MALDI-TOF Mass Spectrometry, 183
SELDI Mass Spectrometry, 184
ICP Mass Spectrometry, 184
Proteomics, 184
ANALYTICAL PROBLEM OF ION SUPPRESSION, 185

8 **Principles of Clinical Enzymology**, 191
Renze Bais, Ph.D., and Mauro Panteghini, M.D.

BASIC PRINCIPLES, 191
Enzyme Nomenclature, 191
Enzymes as Proteins, 192
Enzymes as Catalysts, 198
ENZYME KINETICS, 198
The Enzyme-Substrate Complex, 198
Factors Governing the Rate of Enzyme-Catalyzed Reactions, 199
ANALYTICAL ENZYMOLOGY, 207
Measurement of Reaction Rates, 207
Units for Expressing Enzyme Activity, 209
Measurement of Substrates, 209
Optimization, Standardization, and Quality Control, 210
Measurement of Enzyme Mass Concentration, 211
Enzymes as Analytical Reagents, 211
Analytical Applications of Immobilized Enzymes, 213
Measurement of Isoenzymes and Isoforms, 213

DIAGNOSTIC ENZYMOLOGY, 214
Factors Affecting Enzyme Levels in Plasma or Serum, 214
Selection of Enzyme Tests, 216

9 Principles of Immunochemical Techniques, 219
L.J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path.

BASIC CONCEPTS, 219
Antibodies, 219
Immunogens, 220
ANTIGEN ANTIBODY BINDING, 221
Binding Forces, 221
Reaction Mechanism, 222
Factors Influencing Binding, 222
Types of Reactions, 223
QUALITATIVE METHODS, 224
Passive Gel Diffusion, 224
Immunoelectrophoresis (IEP), 225
Western Blotting, 227
Dot Blotting, 228
QUANTITATIVE METHODS, 229
Radial Immunodiffusion and Electroimmunoassay, 229
Turbidimetric and Nephelometric Assays, 230
Labeled Immunochemical Assays, 230
Interferences in Immunoassays, 239
OTHER IMMUNOCHEMICAL TECHNIQUES, 239
Immunocytochemistry, 239
Agglutination Assays, 240

10 Nanotechnology and Microfabrication, 245
Peter Wilding, Ph.D., F.R.C.Path., F.R.S.C., H.C.L.D.(A.B.B.)

BACKGROUND, 246
FABRICATION AND MATERIALS, 247
Manufacturing Techniques, 247
Drilling, 249
Bonding and Sealing, 249
MICROFLUIDICS, 250
VALVING SYTEMS, 250
APPLICATIONS, 252
Genomics, 252
Hybridization Arrays, 253
Nucleic Acid Sequencing, 254
Drug Detection and Assay, 254
Protein Chips, 254
Immunoassay for Antibodies and Peptides, 255
Enzymology, 255
Metabolites, 255
Cell Handling and Cell Culture, 256
Other Applications, 256
SURFACE CHEMISTRY ISSUES, 256
LIMITATIONS OF MICROTECHNOLOGY, 257
THE FUTURE, 257

11 Automation in the Clinical Laboratory, 265
James C. Boyd, M.D., and Charles D. Hawker, Ph.D., M.B.A., F.A.C.B.

HISTORICAL OVERVIEW, 265
Processes Used in Automation, 266
Laboratory Information Systems, 266
Robotics, 267
Types of Automation, 267
INDIVIDUAL STEPS IN THE ANALYTICAL PROCESSES, 267
Specimen Acquisition, 268
Specimen Identification, 268
Specimen Delivery to Laboratory, 270
Specimen Preparation, 271
Specimen Loading and Aspiration, 271
On-Analyzer Specimen Delivery, 272
Reagent Handling and Storage, 273
Reagent Delivery, 274
Chemical Reaction Phase, 274
Measurement Approaches, 276
INTEGRATED AUTOMATION FOR THE CLINICAL LABORATORY, 280
Workstations, 281
Instrument Clusters, 281
Workcells, 282
Automated Specimen Transport, 282
Automated Specimen Processing, 284
Automated Specimen Sorting, 288
Automated Specimen Storage and Retrieval, 289
PRACTICAL CONSIDERATIONS, 289
Evaluation of Requirements, 289
Problems of Integration, 290
Measuring the Impact of Automation, 292
DEVELOPMENT OF STANDARDS FOR LABORATORY AUTOMATION, 292
OTHER AREAS OF AUTOMATION, 292
Urine Analyzers, 292
Flow Cytometers, 293
Hematology Cell Counters, 293
Nucleic Acid Analyzers, 293
Microtiter Plate Systems, 294
Automated Pipetting Stations, 294
POCT Analyzers, 294
Remote Automated Laboratory System, 294

12 Point-of-Care Testing, 299
Christopher P. Price, Ph.D., and Andrew St. John, Ph.D., M.A.A.C.B.

ANALYTICAL AND TECHNOLOGICAL CONSIDERATIONS, 299
Requirements, 299
Design, 301
Examples of POCT Devices, 303
Informatics and POCT, 308
IMPLEMENTATION AND MANAGEMENT CONSIDERATIONS, 310

FUTURE OF POCT, 315

SECTION III
PRINCIPLES OF LABORATORY MEDICINE

13 Introduction to Laboratory Medicine and Evidence-Based Laboratory Medicine, 323
Christopher P. Price, Ph.D., Patrick M.M. Bossuyt, Ph.D., and David E. Bruns, M.D.

CONCEPTS, DEFINITIONS, AND RELATIONSHIPS, 323
- What Is Laboratory Medicine?, 323
- Clinical Chemistry and Laboratory Medicine, 324
- Clinical Chemistry, Laboratory Medicine, and Evidence-Based Laboratory Medicine, 324

EVIDENCE-BASED MEDICINE—WHAT IS IT?, 324
- Definition and Goals of Evidence-Based Medicine, 324
- The Practice of Evidence-Based Medicine, 325

EVIDENCE-BASED MEDICINE AND LABORATORY MEDICINE, 325
- What is Evidence-Based Laboratory Medicine?, 325
- Types of Diagnostic Questions Addressed in Laboratory Medicine, 326
- Test Results Alone Do Not Produce Clinical Outcomes, 326
- Using the Test Result, 328
- The Clinical Setting of an Outcome Study, 328

CHARACTERIZATION OF DIAGNOSTIC ACCURACY OF TESTS, 328
- Study Design, 328
- The Reporting of Studies of Diagnostic Accuracy and the Role of the STARD Initiative, 329

OUTCOMES STUDIES, 330
- What Are Outcomes Studies?, 330
- Why Outcomes Studies?, 332
- Design of Studies of Medical Outcomes, 333

SYSTEMATIC REVIEWS OF DIAGNOSTIC TESTS, 336
- Why Systematic Reviews?, 336
- Conducting a Systematic Review, 336

ECONOMIC EVALUATIONS OF DIAGNOSTIC TESTING, 338
- A Hierarchy of Evidence, 338
- Methodologies for Economic Evaluations, 338
- Quality of Economic Evaluations, 340
- Perspectives of Economic Evaluations, 340
- Choice of Outcome Measures, 340
- Use of Economic Evaluations in Decision Making, 341

CLINICAL PRACTICE GUIDELINES, 341
- What Is a Clinical Practice Guideline?, 341
- A Transparent Process Must Be Used in the Development of Guidelines, 341
- Steps in the Development of Guidelines, 342
- Obtaining External Review and Updating the Guidelines, 345

CLINICAL AUDIT, 345
- Audit to Help Solve Problems, 346
- Monitoring Workload and Demand, 346
- Monitoring the Introduction of a New Test, 346
- Monitoring Adherence to Best Practice, 347

APPLYING THE PRINCIPLES OF EVIDENCE-BASED LABORATORY MEDICINE IN ROUTINE PRACTICE, 347

14 Selection and Analytical Evaluation of Methods—With Statistical Techniques, 353
Kristian Linnet, M.D., and James C. Boyd, M.D.

METHOD SELECTION, 353
- Medical Criteria, 353
- Analytical Performance Criteria, 354
- Other Criteria, 354

BASIC CONCEPTS IN RELATION TO ANALYTICAL METHODS, 355
- Calibration, 355
- Trueness and Accuracy, 356
- Precision, 357
- Precision Profile, 358
- Linearity, 359
- Analytical Measurement Range, 359
- Limit of Detection, 359
- Analytical Sensitivity, 361
- Limit of Quantitation, 361
- Analytical Specificity and Interference, 361

ANALYTICAL GOALS, 362
- Qualitative Methods, 363

METHOD COMPARISON, 368
- Basic Error Model, 368
- Method Comparison Data Model, 370
- Preliminary Practical Work in Relation to a Method Comparison Study, 371
- Planning a Method Comparison Study, 371
- Distribution of Differences Plot (DoD plot), 371
- Verification of Distribution of Differences in Relation to Specified Limits, 376
- Difference (Bland-Altman) Plot, 376
- A Caution Against Incorrect Interpretation of Paired *t*-Tests in Method Comparison Studies, 377
- Regression Analysis, 378
- Discussion of Application of Regression Analysis, 395
- Discussion of Method Comparison Approaches, 395

MONITORING SERIAL RESULTS, 396

TRACEABILITY AND MEASUREMENT UNCERTAINTY, 397
- Traceability, 397
- The Uncertainty Concept, 398

GUIDELINES, REGULATORY DEMANDS, AND ACCREDITATION, 402

SOFTWARE PACKAGES, 403

15 Clinical Evaluation of Methods, 409
Edward K. Shultz, M.D., M.S., Constantin Aliferis, M.D., Ph.D., and Dominik Aronsky, M.D., Ph.D.

SPECTRUM, 409

CLASSIFICATION BIAS, 410

SENSITIVITY AND SPECIFICITY, 411

RECEIVER OPERATING CHARACTERISTIC CURVES, 412

INTERPRETING A TEST, 413
- Odds Ratio, 413
- Likelihood Ratio, 413
- Bayes' Theorem, 414
- Combination Testing, 415
- Multivariate Data Analysis, 416

Data Analysis Methods for Very Large Numbers of Variables, 418
Clinical Examples, 419
Model Validation, 420
COST EFFECTIVENESS AND OUTCOMES RESEARCH, 420

16 Establishment and Use of Reference Values, 425
Helge Erik Solberg, M.D., Ph.D.

THE CONCEPT OF REFERENCE VALUES, 425
Interpretation by Comparison, 425
Normal Values—An Obsolete Term, 425
Terminology, 426
Types of Reference Values, 426
Requirements, 427
SELECTION OF REFERENCE INDIVIDUALS, 427
Concept of Health in Relation to Reference Values, 427
Strategies for Selection of Reference Individuals, 427
Selection Criteria and Evaluation of Subjects, 430

SECTION IV
ANALYTES

20 Amino Acids, Peptides, and Proteins, 533
A. Myron Johnson, M.D.

AMINO ACIDS, 533
Basic Biochemistry, 533
Clinical Implications, 539
Analysis of Amino Acids, 540
PEPTIDES AND PROTEINS, 541
Basic Biochemistry, 541
Plasma Proteins, 543
Complement Proteins, 564
Immunoglobulins, 569
Proteins in Other Body Fluids, 575
Miscellaneous Proteins, 580
Analysis of Proteins, 582

21 Enzymes, 597
Mauro Panteghini, M.D., Renze Bais, Ph.D., and Wouter W. van Solinge, Ph.D.

MUSCLE ENZYMES, 597
Creatine Kinase, 598
Lactate Dehydrogenase, 601
Aldolase, 603
Glycogen Phosphorylase, 603
LIVER ENZYMES, 604
Aminotransferases, 604
Glutamate Dehydrogenase, 607
Alkaline Phosphatase, 607
5′-Nucleotidase, 611
Gamma-Glutamyl Transferase 612
Glutathione S-Transferase, 613
Cholinesterase, 614
PANCREATIC ENZYMES, 616
Amylase, 616
Lipase, 619
Trypsin, 622
Chymotrypsin, 623
Elastase-1, 623
BONE ENZYMES, 623
Alkaline Phosphatase (Bone Isoform), 624
Acid Phosphatase (Tartrate-Resistant), 624
RED CELL ENZYMES, 625
The Embden-Meyerhof Pathway, 626
Hexose Monophosphate Pathway, 630
Rapoport-Luebering Cycle, 631
Glutathione Pathway, 631
Purine-Pyrimidine Metabolism, 632
Methemoglobin Reduction, 633
Detection of Hereditary Red Cell Enzyme Deficiencies, 633
Methodology, 634

22 Cytokines, 645
Manuel Santos Rosa, Ph.D., and Anabela Mota Pinto, Ph.D.

BACKGROUND INFORMATION, 645
History, 645
Rationale for Measurement, 645
General Characteristics, 646
Nomenclature, 646
Classification, 646
Biochemistry, 647
Cytokine Receptors, 649
Clinical Significance, 649
INDIVIDUAL CYTOKINES, 655
Interleukin-1, 655
Interleukin-2, 660
Interleukin-3, 664
Interleukin-4, 666
Interleukin-5, 669
Interleukin-6, 671
Interleukin-7, 675
Interleukin-8, 676
Interleukin-9, 676
Interleukin-10, 678
Interleukin-11, 680
Interleukin-12, 682
Interleukin-13, 686
Interleukin-14, 688
Interleukin-15, 689
Interleukin-16, 691
Interleukin-17, 693
Interleukin-18, 694

Behavior of Gases, 999
Application of the Henderson-Hasselbalch Equation in Blood Gas Measurements, 1001
Oxygen in Blood, 1002
Tonometry, 1006
Determination of PCO_2, PO_2, and pH, 1006
Temperature Correction of Measured pH, PCO_2, and PO_2, 1013
Continuous and Noninvasive Monitoring of Blood Gases, 1014

28 Hormones, 1019
Michael Kleerekoper, M.D., F.A.C.E., F.A.C.B.

CLASSIFICATION, 1019
Polypeptide or Protein Hormones, 1019
Steroid Hormones, 1019
Amino Acid–Related Hormones, 1019
RELEASE AND ACTION OF HORMONES, 1019
Growth and Development, 1025
Homeostatic Control of Metabolic Pathways, 1025
Regulation of the Production, Use, and Storage of Energy, 1026
ROLE OF HORMONE RECEPTORS, 1026
Cell-Surface Receptors, 1026
Intracellular Receptors, 1027
POSTRECEPTOR ACTIONS OF HORMONES, 1027
Cell-Surface Receptors, 1027
Intracellular Receptors, 1029
CLINICAL DISORDERS OF HORMONES, 1030
MEASUREMENTS OF HORMONES AND RELATED ANALYTES, 1030
Bioassay Techniques, 1030

Receptor-Based Assays, 1030
Immunoassay Techniques, 1030
Instrumental Techniques, 1031

29 Catecholamines and Serotonin, 1033
Thomas G. Rosano, Ph.D., Graeme Eisenhofer, Ph.D., and Ronald J. Whitley, Ph.D.

CHEMICAL STRUCTURE, 1033
BIOSYNTHESIS, RELEASE, AND METABOLISM, 1033
Biosynthesis, 1034
Storage and Release, 1035
Uptake and Metabolism, 1036
PHYSIOLOGY OF CATECHOLAMINE AND SEROTONIN SYSTEMS, 1039
Central Nervous System, 1040
Sympathetic Nervous System, 1041
Adrenal Medullary System, 1043
Peripheral Dopaminergic System, 1044
Enteric Nervous System, 1045
CLINICAL APPLICATIONS, 1045
Pheochromocytoma, 1045
Neuroblastoma, 1049
Dysautonomias and Genetic Disorders, 1050
Carcinoid, 1052
ANALYTICAL METHODOLOGY, 1054
Catecholamines and Metabolites, 1054
Serotonin and Metabolites, 1062

30 Vitamins and Trace Elements, 1075
Alan Shenkin, Ph.D., Malcolm Baines, F.R.S.C., F.R.C.Path., Gordon S. Fell, Ph.D., F.R.C.Path., and T.D.G. Lyon, B.Sc., Ph.D.

NUTRITIONAL ASSESSMENT AND MONITORING, 1076
Protein-Energy Status, 1076
Vitamin and Trace Element Status, 1077
Enzymes or Metabolites, 1077
Markers of Antioxidant Status, 1077
Analytical Factors, 1078
VITAMINS, 1079
Vitamin A, 1079
Vitamin D, 1084
Vitamin E, 1084
Vitamin K, 1087
Vitamin B_1—Thiamine, 1090
Vitamin B_2—Riboflavin, 1094
Vitamin B_6—Pyridoxine, Pyridoxamine, and Pyridoxal, 1097
Vitamin B_{12}—Cyanocobalamin, 1100
Vitamin C—Ascorbic Acid, 1105
Biotin, 1107
Folic Acid, 1109
Niacin and Niacinamide, 1114
Pantothenic Acid, 1116
TRACE ELEMENTS, 1118
Classification, 1118
Dose-Effect Relationships, 1118
Chemistry, 1119
Biochemistry/Homeostasis, 1119
Inborn Errors, 1119
Interactions, 1119
Laboratory Assessment of Trace Element Status, 1120
Analytical Considerations, 1120
Individual Trace Elements, 1122
Other Possibly Essential Elements, 1141

31 Hemoglobin, Iron, and Bilirubin, 1165
Trefor Higgins, M.Sc., Ernest Beutler, M.D., and Basil T. Doumas, Ph.D.

HEMOGLOBIN, 1165
Biochemistry, 1165
Physiological Role, 1169
Analytical Methodology, 1170
Clinical Significance, 1178

Analytical Methodology, 1188
Clinical Significance, 1192
BILIRUBIN, 1193
Chemistry, 1193
Biochemistry, 1194
Analytical Methodology, 1195
Clinical Significance, 1198

32 Porphyrins and Disorders of Porphyrin Metabolism, 1209
Allan C. Deacon, B.Sc., Ph.D., Dip.C.B., F.R.C.Path., Sharon D. Whatley, Ph.D., and George H. Elder, M.D.

PORPHYRIN CHEMISTRY, 1209
Structure and Nomenclature, 1209
Chelation of Metals, 1209
Spectral Properties, 1209
Solubility, 1210
HEME BIOSYNTHESIS, 1211
Enzymes of Heme Biosynthesis, 1211
EXCRETION OF HEME PRECURSORS, 1213
REGULATION OF HEME BIOSYNTHESIS, 1213
ABNORMALITIES OF PORPHYRIN METABOLISM, 1214
The Porphyrias, 1214
Abnormalities of Porphyrin Metabolism Not Caused by Porphyria, 1220
Pseudoporphyria, 1221
LABORATORY DIAGNOSIS OF PORPHYRIA, 1221
Patients With Symptoms of Porphyria, 1221
Relatives of Patients With Porphyria, 1223
ANALYTICAL METHODS, 1223
Methods for Metabolites, 1223
Methods for Blood Porphyrins, 1226
Analysis of Plasma Porphyrins, 1226
Enzyme Measurements, 1226
DNA Analysis, 1229

33 Therapeutic Drugs and Their Management, 1237
Thomas P. Moyer, Ph.D., and Leslie M. Shaw, Ph.D.

DEFINITIONS, 1238
BASIC CONCEPTS, 1238
Mechanism of Action, 1238
Pharmacokinetics, 1240
Drug Disposition, 1243
Clinical Utility, 1247

ANALYTICAL CONSIDERATIONS, 1248
Analytical Techniques, 1248
Issues of Concern, 1249
SPECIFIC DRUG GROUPS, 1249
Antiepileptic Drugs, 1249
Cardioactive Drugs, 1256
Bronchodilators, 1261
Antibiotics, 1262
Antiretrovirals, 1269
Antipsychotic Drugs, 1269
Antimetabolites, 1272
Immunosuppressants, 1274
CLINICAL APPLICATIONS, 1280

34 Clinical Toxicology, 1287
William H. Porter, Ph.D.

BASIC INFORMATION, 1287
Clinical Considerations, 1288
Analytical Considerations, 1289
Toxic Syndromes, 1289
Abstinence Syndromes, 1292
SCREENING PROCEDURES FOR DETECTION OF DRUGS, 1292
Spot Tests, 1292
Determination of Volatiles by Serum Osmol Gap, 1292
Immunoassay, 1293
Planar Chromatography, 1293
Gas Chromatography, 1294
High-Performance Liquid Chromatography, 1296
PHARMACOLOGY AND ANALYSIS OF SPECIFIC DRUGS AND TOXIC AGENTS, 1296
Agents That Cause Cellular Hypoxia, 1296
Alcohols, 1300
Analgesics (Nonprescription), 1304
Drugs Related to the Anticholinergic Toxidrome, 1308
Ethylene Glycol, 1313
Toxic Metals/Iron, 1314
Organophosphate and Carbamate Insecticides, 1315
Drugs of Abuse, 1317
ON-SITE DRUG TESTING, 1350
Sequential Competitive Binding Microparticle Capture Immunoassay, 1350
Homogenous Microparticle Capture Immunochromatography, 1351
Solid Phase Competitive Sequential Enzyme Immunoassay, 1351
Latex-Agglutination-Inhibition Immunoassay, 1351

35 Toxic Metals, 1371
Thomas P. Moyer, Ph.D., Mary F. Burritt, Ph.D., and John Butz, B.A.

BASIC CONCEPTS, 1371
Prevalence of Metal-Based Toxicity, 1371
Diagnosing Toxicity, 1372
Classification of Metals, 1372
Occupational Monitoring, 1373
Analytical Methods, 1373
SPECIFIC METALS, 1374
Aluminum, 1374
Antimony, 1375
Arsenic, 1376
Beryllium, 1377
Cadmium, 1377
Chromium, 1378
Cobalt, 1378
Copper, 1378
Iron, 1379
Lead, 1379
Manganese, 1381
Mercury, 1381
Nickel, 1383
Platinum, 1383
Selenium, 1383
Silicon, 1384
Silver, 1384
Thallium, 1384

SECTION V
MOLECULAR DIAGNOSTICS AND GENETICS

36 Principles of Molecular Biology and Approaches to Nucleic Acid Isolation, 1393
Y.M. Dennis Lo, M.A., D.M., D.Phil., F.R.C.P., F.R.C.Path., and Rossa W.K. Chiu, M.B.B.S., Ph.D., F.R.C.P.A.

LANDMARK DEVELOPMENTS IN GENETICS AND MOLECULAR DIAGNOSTICS, 1393

CHAPTER 1

Introduction to Principles of Laboratory Analyses and Safety*

Edward W. Bermes, Jr., Ph.D., Stephen E. Kahn, Ph.D., and Donald S. Young, M.B., Ph.D.

To reliably perform qualitative and quantitative analyses on body fluids and tissue, the clinical laboratorian must understand the basic *principles and procedures* that affect the analytical process and operation of the clinical laboratory. These include the knowledge of: (1) the concept of solute and solvent, (2) units of measurement, (3) chemicals and reference materials, (4) basic techniques, such as volumetric sampling and dispensing, centrifugation, measurement of radioactivity, gravimetry, thermometry, buffer solution, and processing of solutions, and (5) safety.†

CONCEPT OF SOLUTE AND SOLVENT

Many analyses in the clinical laboratory are concerned with the determination of the presence of or measurement of the concentration of substances in solutions, the solutions most often being blood, serum, urine, spinal fluid, or other body fluids (see Chapter 2).

DEFINITIONS

A *solution* is a homogeneous mixture of one or more *solutes* dispersed molecularly in a sufficient quantity of a dissolving *solvent.* In laboratory practice, solutes are typically measured and are frequently referred to as *analytes.* A solution may be gaseous, liquid, or solid. A clinical laboratorian is concerned primarily with the measurement of gases or solids in liquids, where there is always a relatively large amount of solvent in comparison with the amount of solute.

EXPRESSING CONCENTRATIONS OF SOLUTIONS

The concentration of a solute in a solution may be expressed in different ways (Table 1-1). In the United States, laboratory data typically are reported in terms of mass of solute per unit volume of solution, usually the deciliter. However, the Système International d'Unités (SI) recommends the use of moles of solute per volume of solution for analyte concentrations (substance concentrations), whenever possible, and the use of liter as the reference volume. Although considered incorrect and inappropriate by metrologists, mass concentration also is reported in terms of grams percent or percent. This is typically how concentrations of ethanol in blood are expressed. This terminology indicates an amount of solute per mass of solution (e.g., grams per 100 g) and would be appropriate only if reference materials against which the unknowns were compared were also measured in the same terms. An exception to the general expression of analyte con-

*The authors gratefully acknowledge the original contributions of Drs. Edward R. Powsner and John C. Widman on which the Measurement of Radioactivity portion of this chapter is based.

†Note: Additional discussions on the topics of (1) Chemicals, Reference Materials, and Related Substances, (2) General Laboratory Supplies, (3) Calibration of Volumetric Pipettes, (4) Centrifugation, (5) Procedures for Concentrating Solutions, (6) Separatory Funnels and Extraction Procedures, (7) Laboratory Mixers and Homogenizers, and (8) Filtration are found in the Appendix of this chapter located in the Evolve site that accompanies this book at http://evolve.elsevier.com/Tietz/textbook and in the previous edition of this textbook (Bermes EW, Young DS. In: Burtis CA, Ashwood ER, eds. Tietz textbook of clinical chemistry, 3rd ed. Philadelphia: W.B. Saunders, 1999:3-41.)

TABLE I-1 Concentration Quantities and Units

Name and Quantity	Definition	Unit
Substance concentration (of a given solute component)	Amount of substance of a solute divided by volume of solution	mol/m^3; mol/L
Molality (of a given solute component)	Amount of substance of a solute divided by mass of solvent	mol/kg
Mole fraction (or substance fraction) [of a given component]	Amount of substance of a component divided by amount of substance of mixture (i.e., all components of the system)	mol/mol
Mole ratio (or substance ratio) [of a given solute component]	Amount of substance of a solute divided by amount of substance of the solvent	mol/mol
Mass concentration (of a given component)	Mass of a component (e.g., solute) divided by volume of system (e.g., solution)	kg/m^3; kg/L
Mass fraction (of a given component)	Mass of a component divided by mass of system (mixture)	kg/kg
Volume fraction (of a given component)	Volume of a component divided by volume of system (mixture)	m^3/m^3; L/L
Number concentration	Number of specified particles or elementary entities divided by volume of system (mixture)	m^{-3}; L^{-1}
Number fraction	Number of specified particles or elementary entities divided by total number of particles or entities in the system (mixture)	1 (a ratio)
Substance content (of a given component)	Amount of substance of a component divided by mass of system (mixture)	mol/kg

From The SI for the Health Professions, World Health Organization, 1977.

centrations in terms of volume of solution is the measurement of osmolality, in which concentrations are expressed in terms of mass of solvent (mOsmol/kg or mmol/kg).

When the solution and solvent are both liquids, as in alcohol solutions, the concentration of such a solution is frequently expressed in terms of volume per volume (vol/vol).[33] By adding 70 mL of alcohol to a flask and mixing it to 100 mL with water, a solution whose concentration is 700 mL/L would be achieved. The expression "700 mL/L" is preferred to the alternatives of 70 volumes percent or 70% (vol/vol).

The following equations define the expressions of concentrations:

$$\text{Mole} = \frac{\text{mass (g)}}{\text{gram molecular weight (g)}}$$

$$\text{Molarity of a solution} = \frac{\text{number of moles of solute}}{\text{number of liters of solution}}$$

$$\text{Molality of a solution} = \frac{\text{number of moles of solute}}{\text{number of kilograms of solvent}}$$

$$\text{Normality of a solution} = \frac{\text{number of gram equivalents of solute}}{\text{number of liters of solution}}$$

$$\text{Normality (in oxidation–reduction reaction)} = \text{molarity} \times \text{difference in oxidation state}$$

$$\text{Gram equivalent weight (as oxidatant or reductant)} = \frac{\text{formula weight (g)}}{\text{difference in oxidation state}}$$

For example, using these equations, a 1 *molar* solution of H_2SO_4 contains 98.08 g H_2SO_4 per liter of solution. (Note: The symbol M, to denote molarity, is no longer acceptable and has been replaced by mol/L.) A *molal* solution contains 1 mol of solute in 1 kg of solvent. Molality is properly expressed as mol/kg.

Likewise, a one *normal* solution contains 1 g equivalent weight of solute in 1 L of solution; for example, 1 mol HCl, 0.5 mol H_2SO_4, and 0.33 mol H_3PO_4, each in 1 L of solution, are one normal solutions. The use of normality is limited in that a given solution may have more than one normality, depending on the type of reaction for which the solution is used. The molarity of a solution, however, is a fixed number because there is only one molecular mass for any substance. Normality is no longer recommended to express concentrations. Nevertheless, the term is included here because it remains in common usage and is related to the equivalent concept sometimes favored for serum electrolyte concentrations in the United States and some other countries.

A milligram equivalent of a substance is its equivalent weight expressed in milligrams. The equivalent mass of H_2SO_4 is 49.04 g; therefore 1 mg equivalent of H_2SO_4 =

49.04 mg H_2SO_4. Because substances may react on the basis of their valence, 1 mol calcium (atomic weight = 40), which is bivalent, has twice the combining power of 1 mol sodium (atomic weight = 23). Forty mg calcium is therefore equivalent to 46 mg sodium.

An older unit of measurement used to express the concentration of electrolytes in plasma is the milliequivalent (mEq), which is one thousandth of an equivalent.

$$\text{Milliequivalents (mEq)} = \frac{\text{weight (g)}}{\text{milliequivalent mass (g)}}$$

Milligrams per 100 mL (deciliter) can be converted to mEq per liter using the following formula:

$$\text{mEq/L} = \frac{\text{mg/dL} \times 10 \times \text{valence}}{\text{mg atomic mass}}$$

Example: If the serum sodium concentration is 322 mg/dL, then the serum contains 3220 mg/L. The equivalent mass of sodium is 23, and the valence is 1; therefore:

$$\text{mEq/L} = \frac{322 \times 10 \times 1}{23} = 140$$

The *recommended* units for sodium concentration in plasma are millimoles per liter (mmol/L). In the previous example, the concentration of sodium is:

$$\text{mmol/L} = \frac{\text{mg/L}}{\text{mg molecular mass}} = \frac{322 \times 10 \times 1}{23} = 140$$

In chemical terms, the *titer* of a solution is the mass of a substance equivalent to a unit volume of the solution.

$$\text{Titer} = \frac{\text{grams of substance}}{\text{liters of solution}} = \frac{\text{mg substance}}{\text{mL solution}}$$

However, in clinical laboratory practice, a titer is more commonly thought of as the lowest dilution at which a particular reaction takes place. Titer is customarily expressed as a ratio, for example, 1:10 or 1 to 10.

Regarding gases in solution, Henry's law states that the solubility of a gas in a liquid is directly proportional to the pressure of the gas above the liquid at equilibrium. Thus as the pressure of a gas is doubled, its solubility is also doubled. The relationship between pressure and solubility varies with the nature of the gas. When several gases are dissolved at the same time in a single solvent, the solubility of each gas is proportional to its partial pressure in the mixture. The solubility of most gases in liquids decreases with an increase in temperature and indeed boiling a liquid frequently drives out all dissolved gases. Traditionally the unit used to describe the concentration of gases in liquids has been percent by volume (vol/vol). Using the SI, gas concentrations are expressed in moles per cubic meter (mol/m^3).

UNITS OF MEASUREMENT

A meaningful measurement is expressed with both a number and a unit. The unit identifies the dimension—mass, volume, or concentration—of a measured property. The number indicates how many units are contained in the property.

TABLE 1-2 SI Base Units

Quantity	Name	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd
Catalytic amount	katal	kat

Traditionally, measurements in the clinical laboratory have been made in metric units. In the early development of the metric system, units were referenced to length, mass, and time. The first absolute systems were based on the centimeter, gram, and second (CGS) and then the meter, kilogram, and second (MKS). The SI is a different system that was accepted internationally in 1960. The *units of the system* are called SI units.

The SI takes its origin from the Conférence Générales des Poids et Mesures (CGPM), which since 1889 has functioned as the international authority for measurement. Operating under CGPM is the Comité International des Poids et Mesures (CIPM), whose prime responsibilities are to define units and to direct the Bureau International des Poids et Mesures (BIPM). The BIPM, established in 1875, serves as the international reference laboratory and has the responsibility for ensuring uniformity of physical measurements.

INTERNATIONAL SYSTEM OF UNITS[38]

There are three classes of SI units: base, derived, and supplemental units. A *base unit* was decreed by the CGPM for each of eight fundamental but dimensionally independent physical quantities. These units are listed in Table 1-2. A *derived unit* is derived mathematically from two or more base units (Table 1-3). A *supplemental unit* is a unit that conforms to the SI but that has not been classified as either base or derived. At present only the radian (for plane angles) and the steradian (for solid angles) are classified this way.

The CGPM recognizes that some units outside the SI continue to be important and useful in particular applications. An example is the liter as the reference volume in clinical analyses. Liter is the name of the submultiple (cubic decimeter) of the SI unit of volume, the cubic meter. Considering that 1 cubic meter represents some 200 times the blood volume of an adult human, the SI unit of volume is neither a convenient nor a reasonable reference volume in a clinical context. Nevertheless, the CGPM recommends that such exceptional units as the liter should not be combined with SI units and preferably should be replaced with SI units whenever possible.

TABLE 1-3 Examples of SI-Derived Units Important in Clinical Medicine, Expressed in Terms of Base Units

Quantity	Name	SI Symbol	Expression in Terms of Other SI Units	Expression in Terms of SI Base Units
Volume	cubic meter	m^3		m^3
Mass density	kilogram per cubic meter	kg/m^3		kg/m^3
Concentration of amount of substance	mole per cubic meter	mol/m^3		mol/m^3
Frequency	hertz	Hz		s^{-1}
Force	newton	N		$m \cdot kg \cdot s^{-2}$
Pressure	pascal	Pa	N/m^2	$m^{-1} \cdot kg \cdot s^{-2}$
Energy, work, quantity of heat	joule	J	$N \cdot m$	$m^2 \cdot kg \cdot s^{-2}$
Power	watt	W	J/sec	$m^2 \cdot kg \cdot s^{-3}$
Electric potential, potential difference, electromotive force	volt	V	$W \cdot A^{-1}$	$m^2 \cdot kg \cdot s^{-3} \cdot A^{-1}$

TABLE 1-4 Non-SI Units Retained for Use with the SI

Quantity	Unit	Symbol	Value in SI Units
Time	minute	min	1 min = 60 s
	hour	h	1 h = 3600 s
	day	d	1 d = 86,400 s
Plane angle	degree	°	$1° = \pi/180$ rad
	minute	′	$1' = \pi/10{,}800$ rad
	second	″	$1'' = \pi/648{,}000$ rad
Volume	liter	L	1 L = 1 dm^3 or 10^{-3} m^3
Mass	tonne	t	1 t = 1000 kg

The minute, hour, and day have had such long-standing use in everyday life that it is unlikely that new SI units derived from the second could supplant them. Some other non-SI units are still accepted, although they are rarely used by most individuals in their daily lives but have been very important in some specialized fields. Examples of such units are the nautical mile, knot, and hectare. Examples of non-SI units retained for use with the SI are illustrated in Table 1-4.

Decimal Multiples and Submultiples of SI Units

In practical application of SI units, certain values are too large or too small to be expressed conveniently in the base or derived units. Numerical values can be brought to convenient size when the unit is appropriately modified by official SI prefixes. In general the prefixes are such that the value of the unit changes 1000-fold. However, certain common previously accepted multiples or submultiples, such as deci- and hecto-, are still accepted in the SI framework. The SI prefixes are listed in Table 1-5 together with their symbols.

The International Organization for Standards (ISO) recommends that prefix symbols be printed in Roman (upright) type without spacing between the prefix symbol and the unit symbol, thus mL rather than m L. Furthermore, an exponent attached to a symbol containing a prefix indicates that the multiple or submultiple of the unit is raised to the power expressed by the exponent (e.g., cm^3 is 10^{-6} m^3). Compound prefixes formed by the juxtaposition of two or more SI prefixes are not to be used. Thus 1 nm is appropriate, whereas 1 mμm is not. Likewise, the appropriate unit of mass is the megagram (Mg) rather than the kilokilogram (kkg).

Applications of SI in Laboratory Medicine

Many international clinical laboratory organizations and national professional societies have accepted the SI units in its broad application. The World Health Organization has also recommended its adoption. These organizations have accepted the liter as the preferred unit of volume. For multiples and submultiples of units, including derived units, only one prefix should be used. The prefix should preferably be confined to the numerator, except in the case of the kilogram. Units of concentration should use the liter as denominator. Use of the milli-, micro-, or femtoliter for reporting of test values requires little alteration in thinking when liter is used for reporting mass concentrations, provided that the numerator unit is changed by a similar factor. The numerator unit is usually adjusted so that clinically probable values are less than 1000. When liter is used instead of deciliter for reporting of results, their numerical value is increased by a factor of 10. Such values, when considered in conjunction with the patient's clinical status, should be understandable.

Use of the liter as reference volume causes little confusion in interpretation of test results. However, introduction of the concept of amount of substance expressed as mole (mol) and

TABLE 1-5 Metric Prefixes of SI Units*

Factor	Prefix	Symbol	Factor	Prefix	Symbol
10^{24}	yotta	Y	10^{-1}	deci	d

From The International System of Units [SI]. Washington, DC, National Institute of Standards and Technology, 1991.
*The Eleventh Conférence Générale des Poids et Mésures (CGPM) (1960, Resolution 12) adopted a first series of prefixes and symbols of prefixes to form the names and symbols of the decimal multiples and submultiples of SI units. Prefixes for 10^{-15} and 10^{-18} were added by the twelfth CGPM (1964, Resolution 8), those for 10^{15} and 10^{18} by the fifteenth CGPM (1975, Resolution 10), and those for 10^{21}, 10^{24}, and 10^{-24} were proposed by the CIPM (1990) for approval by the nineteenth CGPM (1991).
†Outside the United States, the spelling "deca" is used extensively.

TABLE 1-6 Typical Values for Analytes and Reporting Increments

	Conventional Units	Recommended Units	Rounded Recommended Units	Smallest Recommended Reporting Increment
Albumin	3.8 g/dL	550.6 μmol/L	550.0 μmol/L	10.0 μmol/L
Bilirubin	0.2 mg/dL	3.42 μmol/L	3 μmol/L	2 μmol/L
Calcium	9.8 mg/dL	2.45 mmol/L	2.45 mmol/L	0.02 mmol/L
Cholesterol	200 mg/dL	5.17 mmol/L	5.2 mmol/L	0.05 mmol/L
Creatinine	0.8 mg/dL	90.48 μmol/L	90 mmol/L	10 μmol/L
Glucose	90 mg/dL	5.00 mmol/L	5.0 mmol/L	0.1 mmol/L
Phosphorus	3.0 mg/dL	0.97 mmol/L	1.0 mmol/L	0.05 mmol/L
Thyroxine	7.0 μg/dL	90.09 nmol/L	90 nmol/L	10 nmol/L
Triglycerides	100 mg/dL	1.14 mmol/L	1.15 mmol/L	0.05 mmol/L
Urea nitrogen*	10 mg/dL	3.57 mmol/L	3.5 mmol/L	0.05 mmol/L
Uric acid	5.0 mg/dL	297 μmol/L	300 μmol/L	10 μmol/L

*Urea nitrogen is reported as urea (mmol/L) when SI units are used.

its decimal fractions of mmol, μmol, nmol, and so on, could lead to confusion because of general lack of familiarity with these units in comparison with more traditional units. The SI does not mandate the use of amount of substance (moles) or substance concentration (moles per liter) instead of mass of substance (kilograms) or mass concentration (kilograms per liter). However, in those countries in which the SI has been introduced into medical practice, amounts of constituents of body fluids are usually reported as substance concentrations rather than mass concentrations, for example, 2.5 mmol/L instead of 10 mg/dL for calcium and 3.9 mmol/L instead of 70 mg/dL for glucose. The rationale for this change is that compounds react on a molar basis, and expression of amounts of substances in such terms allows a better understanding of the relative proportion of compounds. Even though physicians initially have little comprehension of the meaning of results when expressed in units of substance concentration, experience in other countries has shown that they soon adjust to the previously unfamiliar units. Nevertheless, during and after the transition from one set of units to another, it is essential that numbers be unequivocally associated with units. There is therefore no cause for misinterpretation. A comparison of results of some of the commonly measured serum constituents, at a concentration found in healthy individuals, is shown in Table 1-6.

Problem Areas in the Use of SI Units

Problems in the implementation of SI units in the clinical laboratory have been encountered in the following areas.

Expressing Acidity

Some individuals have advocated reporting of *acidity* of body fluids in terms of hydrogen ion concentration instead of pH. Their rationale is that pH is a measure of the chemical potential of hydrogen ions rather than a measure of the concentration of the ions. Because chemical potential is a function of the activity coefficient, which is not known with certainty, the antilog of pH cannot be assumed to equal the hydrogen ion concentration. pH values should be treated as primary variables and reported as measured.

Expressing Enzyme Units

The base unit katal (symbol kat), mol/sec, is the *catalytic amount* of any catalyst, including enzymes, that catalyzes a reaction rate of 1 mol per second in an assay system.* The kind of quantity measured is identified as catalytic amount. There is a constant relationship between the international unit (1 μmol/min) and the katal (1 mol/sec); to convert a value in international units to nmol/sec, the value is multiplied by 16.67. Note, however, that dependence on reaction conditions applies to SI units in the same way as to international units; therefore data reported in the same units but obtained under different conditions may not be comparable. Replacement of the international unit for reporting enzyme activity is likely to be slow; even units that antedated the international unit are sometimes used in clinical laboratory practice. (See Chapters 8 and 21 for further details on the expression of enzyme activity.)

Expressing Protein Concentration

For some *proteins* whose molecular weight is uncertain, debate continues as to the appropriate unit for reporting test results. Nevertheless, because substance concentration gives a better indication of the relative amount of a protein, substance concentration units are still preferred, even if the molecular weight of the protein is not exactly known. The molecular weight actually used for the substance concentration should be included as part of the test description. The concentration of *hormones* should also be reported as substance concentration. Units of activity, such as international units related to a consensus standard, should be avoided. Again, where uncertainty in the correct molecular weight of the hormone exists, an approximate value may be used without introducing a major error in the reported results. Even though the molecular weight of hemoglobin is known, there is no agreement as to whether the monomer Hb(Fe), or the tetramer $Hb_4(Fe_4)$, should be used to report values as substance concentration. Until agreement is reached, the International Committee for Standardization in Hematology (ICSH) recommends that hemoglobin results be reported in terms of mass concentration, i.e., grams per liter (g/L).

Expressing Drug Concentration

Although it is probable that *drugs* will be prescribed and administered in mass units for the immediate future, it is still desirable that the concentration of a drug in a body fluid be expressed in terms of substance concentration rather than mass concentration. Substance concentration allows the concentration of a drug to be understood in comparison with the concentrations of proteins, to which drugs are largely bound, and of other compounds with which drugs compete for protein-binding sites. For drugs it is essential that units be clearly stated to prevent dangerous misinterpretations of test values, which might occur when drugs are administered and measured in body fluids in different units.

Expressing Osmolality

The osmole is not an SI unit and therefore theoretically is not suitable for reporting results of measurements of the concentration of osmotically active particles. The appropriate alternatives would be to record the depression of freezing point, whose unit is kelvin or degree Celsius, or the change in vapor pressure in pascals. But because the units would be method dependent, some of the benefits of using the osmole would be lost. The current recommendation is to report osmolality in moles per kilogram (mol/kg). If osmolarity is reported, the preferred unit remains moles per liter (mol/L).

Expressing Units of Energy

Implementation of the SI requires the use of the joule (J) to replace the calorie as the unit of *energy*. The calorie, as now used, is an ill-defined unit. The terms "calorie" and "Calorie," widely used in nutrition practice, actually relate to the thermochemical kilocalorie. Thus replacement of calorie by joule would prevent confusion and introduce a uniform practice. Resistance to conversion from calories to joules is based on the same arguments that have been used against the change from other traditional units to SI units. The arguments, in the case of energy units, also cite the lack of published tables of nutrition information in SI units. It is recommended that dietary allowances be presented in megajoules rather than kilojoules, because the smaller number probably has some psychological benefit to the dieter. A 2000-kilocalorie diet seems more acceptable when expressed as 8.37 MJ than as 8370 kJ.

Expressing Units of Pressure

The correct unit for reporting *pressure*, whether it is the partial pressure of blood gases or blood pressure, is the pascal. Because the numerical values expressed in pascals are too small to be used for most clinically important pressure

*In 1999, with passage of Resolution 12 of the 21st CGPM, the katal became an official international unit. With its formal adoption, metrologists expect that the katal will eventually replace the non-SI "unit." However, currently, "units" are more commonly used than the katal.

measurements, the kilopascal is a more convenient unit. Thus kilopascal replaces mm Hg or torr. The present common units for gas concentrations in blood are volume percent (vol%) or mmol/L. The carbon dioxide content of blood is expressed in mmol/L. If all the carbon dioxide in the blood were in the form of bicarbonate, mEq/L of bicarbonate and mmol/L of carbon dioxide would be identical. Because carbon dioxide exists in the blood as a mixture of free CO_2, HCO_3^-, and H_2CO_3, concentrations of carbon dioxide are best reported in mmol/L.

Conversion Rules

To convert from conventional units to SI units, the following scheme may be used:

1. Mass concentration (mass units/dL) to mass concentration (mass units/L):

   Numerical value in mass units/dL × 10 = mass units/L

   e.g., Serum albumin, 4.0g/dL × 10 = 40g/L

2. Mass concentration to substance concentration:

$$\frac{\text{Numerical value in mass concentration/dL}}{\text{molecular mass}} \times 10 = \text{substance units/L}$$

$$\text{e.g., Serum albumin, } 4.0\,\text{g/dL} = \frac{4.0 \times 10}{69{,}000\,\text{mol/L}} = 580\,\mu\text{mol/L}$$

3. Mass amount to amount of substance:

$$\frac{\text{Numerical value in mass units}}{\text{molecular mass}} = \text{amount of substance}$$

$$\text{e.g., Urine albumin, } 150\,\text{mg/d} = (150/69{,}000)\,\text{mmol/d} = 2.2\,\mu\text{mol/d}$$

$$\text{Urine urate, } 600\,\text{mg/d} = 600/168 = 3.6\,\text{mmol/d}$$

In some cases, a factor of 1000 may be required so that values in SI units generally fall between 1 and 1000. To convert from SI to conventional units the reverse process of that shown previously is used.

The factors for converting from traditional to SI units for many of the constituents of body fluids commonly measured in the clinical laboratory are listed in the table of reference intervals in Chapter 56.

Standardized Reporting of Test Results

To describe test results properly, it is important that all necessary information be included in the test description. Systems developed for expressing the results produced by the clinical laboratory include the Logical Observation Identifier Names and Codes (LOINC) system and the International Federation of Clinical Chemistry/International Union of Pure and Applied Chemistry (IFCC)/IUPAC system.

LOINC System

The LOINC system is a universal coding system for reporting laboratory and other clinical observations to facilitate electronic transmission of laboratory data within and between institutions (http://www.loinc.org).[13,23] This set of codes was developed by an ad hoc group of clinical chemists, clinical pathologists, and representatives from the diagnostic industry. It was supported in part by grants and contracts from the John A. Hartford Foundation of New York, the U.S. National Library of Medicine, the Agency for Health Care Policy and Research, and the Regenstrief Institute for Healthcare. These codes are intended to be used in context with existing standards, such as ASTM E1238 (American Society for Testing and Materials),[2] HLV Version 2.2. (Health Level Seven),[19] and the Systematized Nomenclature of Medicine, Reference Technology (SNOMED-RT).[52] A similar standard, known as CEN ENV 1613, is being developed by the European Committee for Standardization of the Comité Européen de Normalisation (CEN) Technical Committee 251[10] (http://www.cenorm.be).

The LOINC data base currently carries records for greater than 30,000 observations.[23] For each observation, there is a code, a long formal name, a short 30-character name, and synonyms. A mapping program termed "Regenstrief LOINC mapping assistant" (RELMA) is available to map local test codes to LOINC codes and to facilitate searching of the LOINC data base. Both LOINC and RELAM are available at no cost from http://www.regenstrief.org/loinc/.

IFCC/IUPAC System[50]

The IFCC/IUPAC system recommends that the following items be included with each test result:

1. The name of the system or its abbreviation
2. A dash (two hyphens)
3. The name of the analyte (never abbreviated) with an initial capital letter
4. A comma
5. The quantity name or its abbreviation
6. An equal sign
7. The numerical value and the unit or its abbreviation

The following example illustrates a correct description of a test result in complete and abbreviated forms for the IFCC/IUPAC system:

Plasma from fasting patient – glucose, substance concentration = 5.5 millimoles per liter.

Fasting patient(fPt) P-Glucose, substance concentration (substc) = 5.5 mmol/L.

This is not the type of abbreviated information that would appear on a report. This would be:

FPt P-Glucose (substc) = 5.5 mmol/L

The *system* represents the material that is examined. It should be described to the greatest extent necessary to make interpretation of results unambiguous. The system may be the patient, a body fluid, or a component of a body fluid. Although spelling out the system is preferable, certain abbreviations have been recommended by IFCC and IUPAC. The abbreviations may be combined to build up a complete description (e.g., fPt and aB for fasting patient or arterial blood, respectively). The abbreviations recommended by the

IFCC, IUPAC, and other organizations are listed in Table 1-7. The different kinds of quantities used and their accepted abbreviations are listed in Table 1-8.

CHEMICALS AND REFERENCE MATERIALS

The quality of the analytical results produced by the laboratory is a direct indication of (1) the purity of the chemicals used as analytical reagents and (2) the availability and quality of the reference materials used to calibrate assays and to monitor their analytical performance. Laboratory chemicals are available in a variety of grades. The solutes and solvents used in analytical work are *reagent grade chemicals,* among which water is a solvent of primary importance. IUPAC has established criteria for "primary standards." The National Institute of Standards and Technology (NIST; http://ts.nist.gov/ts/htdocs/230/232/232.htm) has a number of Standard Reference Materials (SRMs) available for the clinical chemistry laboratory. The National Committee for Clinical Laboratory Standards (NCCLS; http://www.ncccls.org) has established a standard for reagent grade water[34] and has published several documents that describe and discuss the use of reference materials in clinical laboratory medicine and their role in the National Reference System for the Clinical Laboratory.[29-31] Certified reference materials of clinical relevance are also available from the Institute for Reference Materials and Measurements (IRMM) in Geel, Belgium (http://www.irmm.jrc.be/)[49] and the World Health Organization (WHO; http://www.who.int/biologicals/IBRP/Catalogue.htm).

Reagent Grade Water

The preparation of most reagents and solutions used in the clinical laboratory requires "pure" water. In the distant past, the term "distilled" has been used to mean "pure," because distillation was the principal procedure used to remove the impurities that water contains in its natural state. Now there are alternative, cost effective, methods to produce "pure" water. In fact single-distilled water fails to meet the specifications for Type I Clinical Laboratory Reagent Water put forward by the NCCLS.[34]

Since the term "deionized water" and the term "distilled water" describe preparation techniques, they should be replaced by *reagent grade water,* followed by designation of the Type (I through III), which better defines the specifications of the water and is independent of the method of preparation (Table 1-9).

In general no single process of purification produces water that meets the rigid specifications for reagent grade water type I set forth by the NCCLS. The following processes or any combination of these may be used in the preparation of reagent grade water as long as the final product meets the specifications. The combination selected is usually dictated in part by the quality of the source water and in part by the intended use of the water. In reality most clinical laboratories use reagent water that exceeds the NCCLS specifications.

Preparation of Reagent Grade Water

Distillation, ion exchange, reverse osmosis, and ultraviolet oxidation are processes used to prepare reagent grade water. In practice, water is often filtered before any of these processes are used.

TABLE 1-9 NCCLS Specifications for Reagent Grade Water

	Type I	Type II	Type III
*Microbiological content,** colony forming units per mL, cfu/mL (maximum)	10	10^3	N.A.
pH	N.A.	N.A.	5.0-8.0
Resistivity,† MΩ per centimeter (MΩ-cm), 25 °C	10 (in line)	2.0	0.1
Silicate, mg SiO_2/L (maximum)	0.05	0.1	1.0
Particulate matter‡	Water passed through 0.2-μm filter	N.A.	N.A.
Organics	Water passed through activated carbon	N.A.	N.A.

From National Committee for Clinical Laboratory Standards: Preparation and Testing of Reagent Water in the Clinical Laboratory. 3rd ed. Approved Standard. NCCLS Document C03-A3. Wayne, PA, National Committee for Clinical Laboratory Standards, 1997.

**Microbiological content.* The microbiological content of viable organisms, as determined by total colony count after incubation at 36 ± 1 °C for 14 hr, followed by 48 hr at 25 ± 1 °C, and reported as colony forming units per mL (cfu/mL).

†*Specific resistance or resistivity.* The electrical resistance in ohms measured between opposite faces of a 1-cm cube of an aqueous solution at a specified temperature. For these specifications, the resistivity will be corrected for 25 °C and reported in MΩ/cm. The higher the amount of ionizable materials, the lower the resistivity and the higher the conductivity.

‡*Particulate matter.* When water is passed through a membrane filter with a mean pore size of 0.2 μm, it is considered to be free of particulate matter.

Organic material. When water is passed through a bed of activated carbon, it is considered to contain minimum organic material.

Distillation

Distillation is the process of vaporizing and condensing a liquid to purify or concentrate a substance or to separate a volatile substance from less volatile substances. It is the oldest method of water purification. Problems with distillation for preparing reagent water include the carryover of volatile impurities and entrapped water droplets that may contain impurities into the purified water. This will result in contamination of the distillate with volatiles, sodium, potassium, manganese, carbonates, and sulfates. As a result, water treated by distillation alone does not meet the specific conductivity requirement of type I water.

Ion Exchange

Ion exchange is a process that removes ions to produce mineral-free *deionized water.* Such water is most conveniently prepared using commercial equipment, which ranges in size from small, disposable cartridges to large, resin-containing tanks. Deionization is accomplished by passing feed water through columns containing insoluble resin polymers that exchange H^+ and OH^- ions for the impurities present in ionized form in the water. The columns may contain cation exchangers, anion exchangers, or a "mixed-bed resin exchanger," which is a mixture of cation- and anion-exchange resins in the same container.

A single-bed deionizer generally is capable of producing water that has a specific resistance in excess of 1 MΩ/cm. When connected in series, mixed-bed deionizers usually produce water with a specific resistance that exceeds 10 MΩ/cm.

Reverse Osmosis

Reverse osmosis is a process by which water is forced through a semipermeable membrane that acts as a molecular filter. The membrane removes 95% to 99% of organic compounds, bacteria, and other particulate matter and 90% to 97% of all ionized and dissolved minerals but fewer of the gaseous impurities. Although the process is inadequate for producing reagent grade water for the laboratory, it may be used as a preliminary purification method.

Ultraviolet Oxidation

Ultraviolet oxidation is another method that works well as part of a total system. The use of ultraviolet radiation at the biocidal wavelength of 254 nanometers eliminates many bacteria and cleaves many ionizing organics so they can be removed by deionization.

Quality, Use, and Storage of Reagent Grade Water

Type III water may be used for glassware washing. (Final rinsing, however, should be done with the water grade suitable for the intended glassware use). It may also be used for certain qualitative procedures, such as those used in general urinalysis.

Type II water is used for general laboratory testing not requiring type I water. Storage should be kept to a minimum; storage and delivery systems should be constructed to ensure a minimum of chemical or bacterial contamination.

Type I water should be used in test methods requiring minimal interference and maximal precision and accuracy. Such procedures include trace metal, enzyme, and electrolyte measurements, and preparation of all calibrators and solutions of reference materials. This water should be used immediately after production. No specifications for storage systems for type I water are given because it is not possible to maintain the high resistivity while drawing off water and storing it.

Testing for Water Purity

At a minimum, water should be tested for microbiological content, pH, resistivity, and soluble silica,[1,7,34] and the maximum interval in the testing cycle for purity of reagent water should be 1 week. It should be noted that measurements taken at the time of production may differ from those at the time and place of use. For example, if the water is piped a long distance, consideration must be given to deterioration en route to the site of use. To meet the specifications for high-performance liquid chromatography (HPLC), in some instances it may be necessary to add a final 0.1-μm membrane filter. The water can be tested by HPLC using a gradient program and monitoring with an ultraviolet (UV) detector. No peaks exceeding the analytical noise of the system should be found.

Reagent Grade or Analytical Reagent Grade (AR) Chemicals

Chemicals that meet specifications of the American Chemical Society (ACS) are described as reagent or analytical reagent grade. Currently, ACS is the only organization in the world that sets requirements and develops validated methods for determining the purity of reagent chemicals. These specifications have also become the de facto standards for chemicals used in many high-purity applications. These are available in two forms: (1) lot-analyzed reagents, in which each individual lot is analyzed and the actual amount of impurity reported and (2) maximum impurities reagents, for which maximum impurities are listed. The Committee on Analytical Reagents of the ACS periodically publishes "Reagent Chemicals" listing specifications.[48] Manufacturers of ACS chemicals check each lot in a control laboratory and place "ACS" on the labels only of those lot chemicals that meet the society's published specifications. These reagent grade chemicals are of very high purity and are recommended for quantitative or qualitative analyses.

Ultrapure Reagents

Gas and high-performance liquid chromatographic, fluorometric, electrophoretic, trace metal, and molecular diagnostic analyses frequently call for reagents whose purity exceeds the specifications of those described previously. Manufacturers offer selected chemicals that have been especially purified to meet specific requirements. There is no uniform designation for these chemicals and organic solvents. Terms such as "spectrograde," "nanograde," and "HPLC pure" have been used. Data of interest to the user (e.g., absorbance at a specific UV wavelength) are supplied with the reagent.

Other designations of chemical purity include Chemically Pure *(CP)*; USP and NF Grade (chemicals produced to meet specifications set down in the United State Pharmacopeia [USP] or the National Formulary [NF]). Chemicals labeled purified, practical, technical, or commercial grade should not be used in clinical chemical analysis without prior purification.

Reference Materials

Primary reference materials[29] are highly purified chemicals that are directly weighed or measured to produce a solution whose concentration is exactly known. The IUPAC has proposed a degree of 99.98% purity for primary reference materials.

These highly purified chemicals may be weighed out directly for the preparation of solutions of selected concentration or for the calibration of solutions of unknown strength. They are supplied with a certificate of analysis for each lot. These chemicals must be stable substances of definite composition that can be dried, preferably at 104 ° to 110 °C, without a change in composition. They must not be hygroscopic, so that water is not absorbed during weighing.

Secondary reference materials are solutions whose concentrations cannot be prepared by weighing the solute and dissolving a known amount into a volume of solution. The concentration of secondary reference materials is usually determined by analysis of an aliquot of the solution by an acceptable reference method, using a primary reference material to calibrate the method.

Certified Reference Standards (Standard Reference Materials, SRMs) for clinical laboratories are available from the NIST[39] and the IRMM.[49] Cholesterol, the first SRM developed by the NIST, was issued in 1967. Today, the lists from the NIST and IRMM are extensive (Table 1-10 and Table 1-11, respectively). Not all standard reference materials have the properties and the degree of purity specified for a primary standard, but each has been well characterized for certain chemical or physical properties and is issued with a certificate that gives the results of the characterization.[29-31] These may then be used to characterize other materials.

BASIC TECHNIQUES AND PROCEDURES

Basic practices used in the clinical and molecular diagnostic laboratories include optical, chromatographic, electrochemical, electrophoretic, mass spectrometric, enzymatic, and immunoassay techniques. These techniques are discussed in detail in Chapters 3-9. The specialized techniques used in molecular diagnostic laboratories are discussed in Chapters 36, 37, and 41. Here we discuss the basic techniques of volumetric sampling and dispensing, centrifugation, measurement of radioactivity, gravimetry, thermometry, buffer solutions, and processing solutions.

Volumetric Sampling and Dispensing

Clinical chemistry procedures require accurate volumetric measurements to ensure accurate results. For accurate work, only Class A glassware should be used. Class A glassware is certified to conform to the specifications outlined in NIST circular C-602.[40]

Pipettes

Pipettes are used for the transfer of a known volume of liquid from one container to another. They are designed

Cotinine in human urine (freeze dried)	8444

TABLE 1-11 Reference Materials (RMs) Available from the Institute for Reference Materials and Measurements (www.irmm.jrc.be)

Analyte	RM Number
Lyophilized human serum	BCR-304
Creatinine in human serum	BCR-573, 574, & 575
Latex spheres of certified size (blood cell size)	BCR-165; 166; & 167
Cortisol reference panel	IRMM/IFCC-451
Progesterone in human serum	BCR-347
Estradiol in human serum	BCR-576; 577; 578
Lead and cadmium in blood	BCR-194; 195; 196
Creatine kinase (human placenta)	BCR-299
Gamma-glutamyltransferase (pig kidney)	BCR-319; IRMM/IFCC-452
Alkaline phosphatase (pig kidney)	BCR-371
Lactate dehydrogenase (human isoenzyme)	BCR-404; IRMM/IFCC-453
Prostatic acid phosphatase (human prostate)	BCR-410
Alanine aminotransferase (pig heart)	BCR-426; IRMM/IFCC-454
α-Amylase (human pancreas)	BCR-476; IRMM/IFCC-456
Creatine kinase (human heart)	BCR-608; IRMM/IFCC-455
Adenosine deaminase (human erythrocytes)	BCR-647
Cortisol in human serum	BCR-192; 193
Serum proteins	BCR-470
Glycated hemoglobin	BCR-405
Hemiglobincyanide	BCR-522
Prostate specific antigen	BCR-613
Thromboplastins	BCR-148; 149S
Apolipoproteins	BCR-393; 394
Alpha fetoprotein	BCR-486
Thyroglobulin	BCR-457

either to contain (TC) a specific volume of liquid or to deliver (TD) a specified volume. Pipettes used in clinical, molecular diagnostic, and analytical laboratories include manual transfer and measuring pipettes, micropipettes, and electronic and mechanical pipetting devices. Developments in improved design of pipetting systems include robotic automation, the capability to provide electronic and personal computer (PC) control of pipetting devices, and careful attention to advanced ergonomic design features. There are also automatic photometric pipette calibration systems available[24] that can reduce the time to periodically check pipettes and potentially provide more efficient use of personnel.

Transfer and Measuring Pipettes

A transfer pipette is designed to transfer a known volume of liquid. Measuring and serological pipettes are scored in units such that any volume up to a maximum capacity is delivered. Table 1-12 shows examples of tolerances of various types of these pipettes.

Transfer Pipettes. *Transfer pipettes* include both volumetric and Ostwald-Folin pipettes. They consist of a cylindrical bulb joined at both ends to narrower glass tubing. A calibration mark is etched around the upper suction tube, and the lower delivery tube is drawn out to a gradual taper. The bore of the delivery orifice should be sufficiently narrow so that rapid outflow of liquid and incomplete drainage cannot cause measurement errors beyond tolerances specified.

A volumetric transfer pipette (Figure 1-1, *A*) is calibrated to deliver accurately a fixed volume of a dilute aqueous solution. The reliability of the calibration of the volumetric pipette decreases with a decrease in size, and therefore special micropipettes have been developed.

Ostwald-Folin pipettes (Figure 1-1, *B*) are similar to volumetric pipettes but have their bulb closer to the delivery tip and are used for the accurate measurement of viscous fluids, such as blood or serum. In contrast to a volumetric pipette, an Ostwald-Folin pipette has an etched ring near the mouthpiece, indicating that it is a blow-out pipette. With the use of a pipetting bulb, the liquid is blown out of the pipette only after the blood or serum has drained to the last drop in the delivery tip. When filled with opaque fluids, such as blood, the top of the meniscus must be read. Controlled slow

*Accuracy tolerances for volumetric transfer pipettes are given by ASTM Standard E969.02 "Standard Specification for Glass Volumetric (Transfer) Pipets," West Conshohocken, PA: American Society for Testing of Material, 2003 and Federal Specification NNN-P-395.

†Accuracy tolerances for measuring pipettes are given by Federal Specification NNN-P-350 and for serological pipettes by Federal Specification NNN-P-375.

‡Class A pipettes are manufactured to the highest tolerances. Class B pipettes have tolerances approximately twice that of Class A pipettes.

drainage is required with all viscous solutions so that no residual film is left on the walls of the pipette.

Measuring Pipettes. The second principal type of pipette is the *graduated* or *measuring pipette* (Figure 1-1, *C*). This is a piece of glass tubing that is drawn out to a tip and graduated uniformly along its length. Two kinds are available; the Mohr pipette is calibrated between two marks on the stem, whereas the serological pipette has graduated marks down to the tip. The serological pipette (Figure 1-1, *D*) must be blown out to deliver the entire volume of the pipette and has an etched ring (or pair of rings) near the bulb end of the pipette signifying that it is a blow-out pipette. Mohr pipettes require a controlled delivery of the solution between the calibration marks. Serological pipettes have a larger orifice than do the Mohr pipettes and thus drain faster. In practice, measuring pipettes are principally used for the measurement of reagents and are not generally considered sufficiently accurate for measuring samples and calibrators.

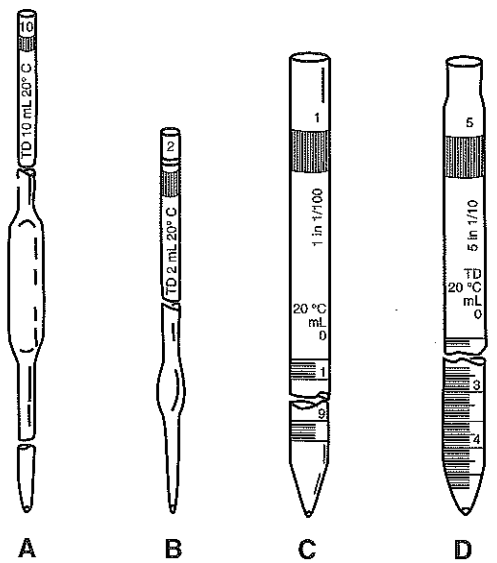

Figure 1-1 Pipettes. **A,** Volumetric (transfer). **B,** Ostwald-Folin (transfer). **C,** Mohr (measuring). **D,** Serological (graduated to the tip).

Pipetting Technique

There are general pipetting techniques that apply to the pipettes described above. For example, pipetting bulbs should always be used, and pipettes must be held in a vertical position when adjusting the liquid level to the calibration line and during delivery. The lowest part of the meniscus, when it is sighted at eye level, should be level with the calibration line on the pipette. The flow of the liquid should be unrestricted when using volumetric pipettes, and the tips should be touched to the inclined surface of the receiving container for 2 seconds after the liquid has ceased to flow.

With graduated pipettes, the flow of liquid may have to be slowed during delivery. Serological pipettes are calibrated to the tip, and the etched glass ring on top of the pipette signifies that it is to be blown out. The pipette is first allowed to drain, and then the remaining liquid is blown out.

TABLE 1-13 Tolerances for Micropipettes

Capacity µL	Accuracy* %	Precision* %	Capacity µL	Accuracy* %	Precision* %
10	1.2	0.4	100	0.5	0.2
40	0.6	0.2	250	0.5	0.15

Micropipettes

Micropipettes are pipettes used for the measurement of microliter volumes. In such devices, the remaining volume that coats the inner wall of a pipette can cause notable error. For this reason, most micropipettes are calibrated to contain (TC) the stated volume rather than to deliver it. Proper use requires rinsing the pipette with the final solution after delivering the contents into the diluent. Volumes are expressed in microliters (µL); the older term *lambda* is no longer recommended. (One lambda [λ] = 1 µL = 0.001 mL.) Micropipettes are generally available in small sizes, ranging from 1 to 500 µL but can be obtained for volumes as low as 0.2 µL. Tolerances for several Eppendorf micropipettes are listed in Table 1-13.

Semiautomatic and Automatic Pipettes and Dispensers

Figures 1-2, *A* and *B* illustrate two types of adjustable micropipetting devices that also demonstrate unique ergonomic design features. These devices are programmable and can be used for dispensing aliquots of liquid into multiple wells at the same time. In practice, using disposable plastic tips, they allow simultaneous aspiration and delivery of solutions to multiple sample micro wells. Each channel is piston driven to allow the user to pipette with as few or as many tips as necessary. Aliquots of liquid as small as 0.2 µL can be dispensed at three different aspiration or dispense rates.

Semiautomatic manual and electronic versions of pipettes and dispensers are available in sizes from 0.5 µL to 10 mL. Figure 1-2, *C* illustrates an electronically operated, positive-displacement multi-channel pipettor. This device draws up and dispenses its predefined volumes (from 0.5 to 200 µL) when its plunger is moved through a complete cycle. Its disposable, fluid containment tips are made of a plastic material that tends to retain less inner surface film than does glass. Such pipettes avoid the risk of cross contamination among samples, eliminate the necessity for washing between samples, and improve the precision of measurements. Models that allow for digital adjustment of the volume aspirated and dispensed are available.

A

Figure 1-2 A, Adjustable volume micropipetting device with ergonomic design.

Figure 1-3, *A* shows an automatic dispensing apparatus that aspirates and dispenses preset volumes of two different liquids by means of two motor-driven syringes, one for metering a volume of the sample and one for metering a volume of the diluent. This device can be adjusted to aspirate as little as 1 µL of one liquid and to deliver it with as much as 999 µL of the other. This type of device, available as a dilutor or dispenser, can be obtained as a manual, electronic, and computer-controlled device. The device is microprocessor controlled and is easily programmed.

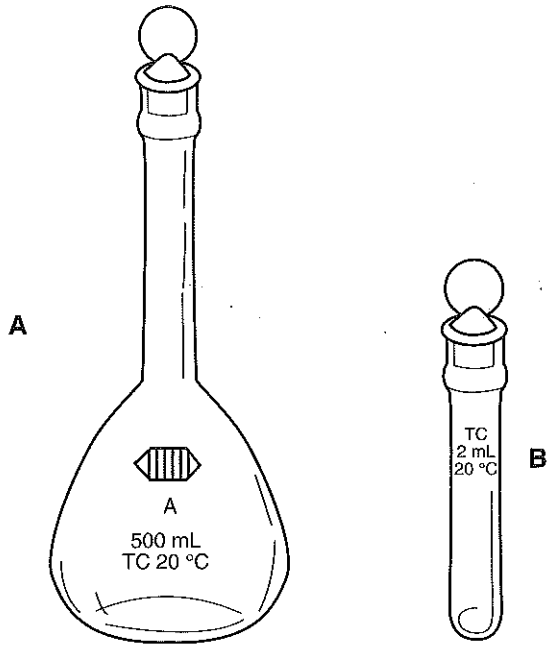

Figure 1-4 Volumetric flasks. **A,** Macro. **B,** Micro.

Twenty-one dispensing programs can be stored in memory and retrieved. This type of liquid dispensing device can also be obtained as a computer-controlled system.

A more versatile piece of equipment is the robotic liquid handling workstation shown in Figure 1-3, *B*, which can be used for clinical chemistry, genomic, proteomic, and other applications. This automated pipetting station can be used with individual reaction tubes and 96- and 384-well microtiter plates. Depending on the design of the system, either a single probe or multiple probes are used rapidly to transfer programmed volumes of solution from one container to microtiter plates (e.g., so that the transfer to all 96 wells can be completed in 1 minute). In some systems, liquid sensing is incorporated into the sample probes to minimize contact with sample and reagents even though automatic washing of the probes is performed between specimens. Two-dimensional (X-Y) movement of probes and tubes or microtiter plates is built into the pipetting stations to minimize the necessity for operator intervention. This device dispenses programmed volumes from 0.5 µL to 1000 µL in serial dilutions from 4 to 16 channels employing an autoloaded system with barcodes for positive identification.

Volumetric Flasks

Volumetric flasks (Figure 1-4) are used to measure exact volumes; they are commonly found in sizes varying from 1 to 4000 mL. In practice, they are primarily used in preparing solutions of known concentration, and they are available in various grades. The most accurate are certified to meet standards set forth by the NIST.

An important factor in the use of volumetric apparatus is the requirement for an accurate adjustment of the meniscus. A small piece of card that is half black and half white is most useful. The card is placed 1 cm behind the apparatus with the white half uppermost and the top of the black area about 1 mm below the meniscus. The meniscus then appears as a clearly defined, thin black line. This device is also useful in reading the meniscus of a burette.

Volumetric equipment should be used with solutions equilibrated to room temperature. Solutions diluted in volumetric flasks should be repeatedly mixed during dilution so that the contents are homogeneous before the solution is made up to final volume. Errors caused by expansion or contraction of liquids on mixing are thereby minimized.

Volumetric flasks should be thoroughly cleaned and dried before calibration. The flask is then weighed and filled with carbon dioxide–free deionized water until just above the graduation mark. The neck of the flask just above the water level should be kept free of water. The meniscus mark is set at the graduation line by removing excess water, and the flask is reweighed. The final weight is corrected for the equilibrated water and air temperature to obtain the volume of the flask. Flasks may also be calibrated by the spectrophotometric technique described below.

Maintenance and Care of Volumetric Glassware

Volumetric glassware and glass apparatus must be absolutely clean to ensure that the volumes measured are accurate, and that the subsequent chemical reactions are not adversely affected. One method that may be used to test for cleanliness is to fill the vessel with distilled water and then empty it and examine the walls to see whether they are covered by a continuous, thin film of water. Imperfect wetting or the presence of discrete droplets of water indicates that the vessel is not sufficiently clean. Obviously, this criterion cannot be used for nonwettable plastics. A test for residual acid or alkaline detergents is the measurement of the pH of water added to the glassware. A dilute solution of an acid-base indicator applied to the surface is another method to check for residual alkaline detergents. The number of pieces of glassware checked depends on the workload and number of pieces cleaned, but at least one piece of randomly selected glassware should be checked each day.

Calibration of Volumetric Pipettes

Accurate calibration and verification of calibration of pipettes, dispensers, and dilutors are important components of a clinical laboratory's quality assurance program. In the past, the gravimetric measurement of the volume of mercury dispensed was the classic procedure used to calibrate such devices. However, owing to the environmental and safety hazards involved with the handling of mercury, this procedure is no longer recommended for use in routine clinical laboratories and has been replaced with gravimetric and spectrophotometric procedures that use aqueous solutions. With the gravimetric procedure, dispensed aliquots of water are weighed with density correction.[18] As an alternative to gravimetric calibration, a spectrophotometric procedure can be used in which aliquots of a compound that absorbs light are pipetted into known volumes of diluent and the

absorbance of the diluted liquid measured (e.g., p-nitrophenol at 401 nm). The volumes of the dispensed aliquots are then computed to verify the calibration of the pipette. In addition, calibration services can be purchased from vendors who advertise their services on the Internet. Examples of gravimetric and spectrophotometric procedures can be found in an earlier edition of this chapter[4] or on the Evolve site that accompanies this book.

CENTRIFUGATION

Centrifugation is the process of using centrifugal force to separate the lighter portions of a solution, mixture, or suspension from the heavier portions. A *centrifuge* is a device by which centrifugation is effected.

In the clinical laboratory, centrifugation is used to:

1. Remove cellular elements from blood to provide cell-free plasma or serum for analysis (see Chapter 2).
2. Concentrate cellular elements and other components of biological fluids for microscopic examination or chemical analysis.
3. Remove chemically precipitated protein from an analytical specimen.
4. Separate protein-bound or antibody-bound ligand from free ligand in immunochemical and other assays (see Chapter 9).
5. Extract solutes in biological fluids from aqueous to organic solvents.
6. Separate lipid components such as chylomicrons from other components of plasma or serum, and lipoproteins from one another (see Chapter 26).

Types of Centrifuges

Horizontal-head or swinging-bucket, fixed-angle or angle-head, ultracentrifuge, and axial are the four types of centrifuges used in the clinical laboratory. In addition, the development of automatic balancing centrifuges, which use hydraulic principles based on Archimedes' and Pascal's laws, has enabled centrifugation to be incorporated as an integral step in the total automation of laboratory testing.[9] As discussed in Chapter 11, such centrifuges are incorporated in various robotized analytical systems that are commercially available.

Horizontal-Head or Swinging-Bucket Centrifuges

This type of centrifuge allows the tubes placed in the cups of the rotor to assume a horizontal plane when the rotor is in motion and a vertical position when it is at rest. During centrifugation, particles travel in a constant manner along the tube while the tube is at right angles to the shaft of the centrifuge; thus the sediment is distributed uniformly against the bottom of the tube. The surface of the sediment is flat (parallel to the shaft of the centrifuge) and remains so, with a column of liquid on top of it when the rotor stops, and the tube assumes a vertical position. Supernatant liquid is removed by a pipette with negligible disturbance of the packed sediment. If the sediment is well packed, the supernatant is decanted.

The spinning rotor of a horizontal-head centrifuge offers considerable resistance to rotation and generates heat as a result of air friction. This resistance is lessened if the swinging buckets are enclosed in a windshield.

Fixed-Angle or Angle-Head Centrifuge

In the rotor of an angle-head centrifuge, tubes are held in a fixed position at angles from 25° to 40° to the vertical axis of rotation. Upon centrifugation, particles are driven outward horizontally but strike the side of the tube so that the sediment packs against the side and bottom of the tube with the surface of the sediment parallel to the shaft of the centrifuge. As the rotor slows down and then stops, gravity causes the sediment to slide down the tube; usually a poorly packed pellet is formed.

Ultracentrifuge

An ultracentrifuge is a very high-speed centrifuge that usually uses fixed-head rotors. The most common application of an ultracentrifuge in the clinical laboratory is the separation of lipoproteins (see Chapter 26). Because the separation may require hours or days and may generate considerable heat as a result of friction at high speeds, ultracentrifugation requires a refrigerated chamber. Ultracentrifuges are available in both analytical and preparative models. A tabletop model is available that is a miniature air turbine with a small rotor capable of achieving a centrifugal force of 165,000 times gravity ($\times g$). It is used in the clinical laboratory to clear serum of chylomicrons so that accurate analyses may be performed on the infranatant.

Axial Centrifuge

An *axial centrifuge* is based on a centrifugal concept that allows tubes of blood to be spun in a vertical orientation as opposed to the horizontal orientation used in traditional centrifuges.[6,12,15,16,45]

Principles of Centrifugation

The correct term to describe the force required to separate two phases in a centrifuge is *relative centrifugal force* (RCF), also called *relative centrifugal field.* Units are expressed as number of times greater than gravity (e.g., $500 \times g$).

RCF is calculated as follows:

$$RCF = 1.118 \times 10^{-5} \times r \times rpm$$

where

1.118×10^{-5} = an empirical factor

r = radius in centimeters from the center of rotation to the bottom of the tube in the rotor cavity or bucket during centrifugation

rpm = the speed of rotation of the rotor in revolutions per minute

The RCF of a centrifuge may also be determined from a nomogram distributed by manufacturers of centrifuges. RCF is derived from the distance from the rotor center to the bottom of the tube, whether the tube is horizontal to, or at an angle to, the rotor center. The RCF as calculated above is

the maximum RCF. However, not all of the contents of a tube are subjected to the maximum RCF. The minimum RCF, calculated in the same way but from the center of rotation to the surface of the liquid, may be several hundred g less than the maximum value. Note also that RCF applied to a tube in a fixed-angle head is much less than that applied to the same tube in a horizontal-head rotor, because the tube in a fixed-angle head is unable to swing outward.

The time required to sediment particles depends on the rotor speed, the radius of the rotor, and the effective path length traveled by the sedimented particles, that is, the depth of the liquid in the tube. Duplication of conditions of centrifugation is often desirable. The following is a useful formula for calculating speed required of a rotor whose radius differs from the radius with which a prescribed RCF was originally defined:

$$\text{rpm (alternate rotor)} = 1000 \times \sqrt{\frac{\text{RCF, original rotor}}{11.18 \times r\,(\text{cm}),\ \text{alternate rotor}}}$$

The length of time for centrifugation can also be calculated so that running with an alternate rotor of a different size is equivalent to running with the original rotor:

$$\text{time (alternate rotor)} = \frac{\text{time} \times \text{RCF (original rotor)}}{\text{RCF (alternate rotor)}}$$

Note, however, that it may not be possible to reproduce conditions exactly when a different centrifuge is used. Descriptions of times of centrifugation include the time for the rotor to reach operating speed (which may vary from instrument to instrument) and do not include deceleration time, during which sedimentation is still occurring but less efficiently. Even with maximal braking, deceleration may take as long as 3 minutes in some centrifuges.

Operation of the Centrifuge

For proper operation of a centrifuge, only those tubes recommended by their manufacturer should be used. The material used for the tube must withstand the RCF to which the tube is likely to be subjected. Polypropylene tubes are generally capable of withstanding RCFs of up to 5000 ×g. The tubes should have a tapered bottom, particularly if a supernatant is to be removed, and should be of a size to fit securely into the rack to be centrifuged. The top of the tube should not protrude so far above the bucket that the swing into a horizontal position is impeded by the rotor.

For smooth operation of the centrifuge, the rotor must be properly balanced. The weight of racks, tubes, and their contents on opposite sides of a rotor should not differ by more than 1% or by an acceptable limit established by the manufacturer. The smaller the difference in weight is, the smoother the centrifugation. Before centrifuging any laboratory specimens, pairs of adapters and specimen tubes should be placed on opposite pans of a balance, and the tubes rearranged so that the weights are equal and the placement of tubes is symmetrical. Tubes filled with water may also be used to equalize the weights. The total weight of each rack should not exceed the limits stated by the centrifuge manufacturer at a rated speed. As discussed earlier, centrifuges that automatically balance their rotors are now available.[9]

Tubes of collected blood should be centrifuged before being unstoppered to reduce the probability of an aerosol being produced when the tube is opened. The practice of using a wooden applicator to release a clot stuck to the top of the tube or to its stopper should be avoided; it is a potential cause of hemolysis. Centrifugation at an appropriate RCF usually ensures that the clot is released from the tube wall and drawn to the bottom of the tube.

Despite years of experience with centrifuges, there are just a few specific recommendations for RCF or time for centrifugation of blood specimens. For example, NCCLS standard H18-A[25] proposes an RCF of 1000 to 1200 × *g* for 10 ± 5 minutes. Standards have not been established for centrifugation of other specimens, such as serum to which a protein precipitant has been added.

Operating Practice[54]

Cleanliness of a centrifuge is important in minimizing the possible spread of infectious agents, such as hepatitis viruses. With proper operation of a centrifuge, few tubes break. In case of breakage, the racks and chamber of the centrifuge must be carefully cleaned. Any spillage should be considered a possible blood-borne pathogen hazard. Gray dust arising from the sandblasting of the chamber by fragments of glass indicates tube breakage and possible contamination, necessitating cleaning of the chamber. Broken glass embedded in cushions of tube holders may be a continuing cause of breakage if cushions are not inspected and replaced in the cleanup procedure.

The speed of a centrifuge should be checked at least once every 3 months. The procedure should use a stroboscopic light or a vibrating-reed external tachometer of known accuracy. The measured speed should not differ by more than 5% from the rated speed under specified conditions. All the speeds at which the centrifuge is commonly operated should be checked. The centrifuge timer should be checked weekly against a reference timer (such as a stopwatch) and should not be more than 10% in error. Commutators and brushes should be checked at least every 3 months. Brushes (where used) should be replaced when they show considerable wear. However, in many modern induction-drive motors, brushes have been eliminated thus removing a source of dust that can cause motor failure.

Because centrifuges generate heat, the temperature in the chamber in many centrifuge models may increase by as much as 5 °C after a single run. The change in temperature depends on the initial ambient temperature in the centrifuge chamber, rotor speed, duration of centrifugation, and rotor design. These factors affect the concentration of analytes in a specimen because of loss of water caused by evaporation. A large chamber around the rotor dissipates heat. When the material to be centrifuged has a labile temperature, a refrig-

erated centrifuge should be used. In the simplest form, a refrigerator unit is mounted beside the centrifuge, and cold air is blown into the rotor chamber. This approach is usually inadequate to stabilize the low temperature. In more sophisticated centrifuges, refrigeration coils around the chamber make it possible to maintain a preset temperature within ±1 °C. The temperature of a refrigerated centrifuge should be measured monthly under reproducible conditions and should be within 2 °C of the expected temperature.

Measurement of Radioactivity

With the development of radioimmunoassays (RIAs) in the 1960s that used radioactive isotopes as labels (see Chapter 9), the measurement of radioactivity became a common and important practice in clinical laboratories. However, concerns about, and problems with, the safe handling and disposal of radioactive reagents and waste have led to the development of immunoassays that use nonisotopic labels (see Chapter 9). The rapid acceptance and extensive use of nonisotopic immunoassays by the clinical laboratory have resulted in a decreased use of RIA and ultimately a decreased requirement for them to measure radioactivity. Because of this deemphasis on the necessity to measure radioactivity, only a brief discussion of the topic is presented here. Readers requiring more detail on this topic are referred to the chapter entitled "Basic Principles of Radioactivity and Its Measurement" that is included in a prior edition of this textbook.[46]

Basic Concepts

An *atom* is the smallest unit of an element having the properties of that element. An individual atom consists of a positively charged nucleus around which revolve negatively charged electrons. The *nucleus* is composed of positively charged protons and neutral neutrons. The *atomic number* (Z) of an element is the number of protons in its nucleus; the total number of nucleons, protons plus neutrons, is its *mass number* (A). A *nuclide* is an atomic species with a given atomic number and a given mass number. *Isotopes* are nuclides with the same atomic number but different mass numbers. These represent various nuclear species of the same element. Radionuclides used in the clinical laboratory are listed in Table 1-14.

Radioactive Decay

Isotopes of a given element have nuclei with the same number of protons but different numbers of neutrons. Some isotopes are stable; however radioisotopes are unstable, disintegrate, and decay by alpha or beta decay, electron capture, or gamma emission and internal conversion.

Radioactive decay is a property of the atomic nucleus and is evidence of nuclear instability. The rate of decay is unaffected by temperature, pressure, concentration, or any other chemical or physical condition but is characteristic of each individual radionuclide.

Alpha Decay. To achieve stable configurations, heavy elements, particularly those with atomic numbers above 70, may shed some of their nuclear mass by emitting a two-proton, two-neutron fragment identifiable after emission as a helium nucleus. Because nuclear radiations were observed before their identity was known, this fragment was called an *alpha* (α-) *particle,* and its emission is termed α-decay. Alpha particles are relatively large in mass, interact strongly with matter, but are absorbed by as little as a sheet of paper. However, because they are so heavy, even with low velocity,

TABLE 1-14 Radiation Properties of Some Radionuclides Used in the Clinical Laboratory

			Maximum Energy of Radiation (MeV)†	
Nuclides	**Half-life**	**Decay Type**	**Beta**	**Gamma**
^{3}H	12.3 y	β^-	0.186	None

^{59}Fe	45 d	β^-	0.475, 0.273	1.10, 1.29
^{99}Mo	66 h	β^-	1.21, 0.450	0.740, 0.181, 0.778
^{99m}Tc	6.0 h	IT	None	0.141
^{125}I	60 d	EC	None	0.035
^{131}I	8.04 d	β^-	0.607, 0.336	0.364, 0.637, 0.284

*β^-, β^+, EC, and IT refer to β-decay, positron decay, electron capture, and isomeric transition, respectively. Where a nuclide is known to have more than one mode of decay, they are listed in the order of their prevalence.

†Energies are given only for the more prevalent β- and γ-radiations and are in approximate order of prevalence. Electron capture (EC) decay also yields the characteristic x-rays of the daughter; the energies of the x-rays are not included in this listing. As noted in the gamma column, positron decay (β^+) is accompanied by annihilation radiation, which consists principally of a pair of 0.511 MeV photons.

their momentum is high. Consequently, they do not travel far, but when they collide with other molecules they do a lot of damage; therefore α-emitters are considered to be quite hazardous.

Beta Decay. For some heavy nuclides and for almost all those with atomic numbers below 60, stability is achieved by a rearrangement of the nucleus in which the total number of nucleons is unchanged. In terms of the neutron-proton model of the nucleus, this rearrangement is the conversion of a neutron to a proton or vice versa. During such conversions, the nucleus emits either a negative electron or its positive equivalent, a *positron.* The emission of the negative electron, named the *beta* (β-) *particle,* is what is usually meant by the term β-*decay.*

The emission of a negative β-particle leaves the nucleus with one additional positive charge, a neutron is converted to a proton, and the nucleus assumes the next higher atomic number. Negative β-emission is characteristic of a nucleus that has more neutrons than required by its protons for stability. For example, tritium is an unstable isotope of hydrogen (^{3}H), consisting of a proton, an electron, and two neutrons. When an atom of tritium decays, one of the neutrons is converted to a proton, one β-particle and one neutrino are released, and a helium isotope (^{3}He) remains. Tritium is called a "soft" β-emitter, because its β-particles have relatively low velocities. A hard β-emitter, such as *phosphorus* 32 (^{32}P) is more hazardous because its β-particles carry more kinetic energy; however, it is easier to detect.

Other examples of nuclides that decay by negative β-emission are carbon-14(^{14}C), iron-59 (^{59}Fe), and iodine-131 (^{131}I). Negatively charged β-particles are smaller in mass and interact less with matter than β-particles, easily penetrate paper and cardboard, but are absorbed by metal sheets.

Electron Capture. An alternative decay process to the emission of positive β-particles is the capture of an electron. In this process, an orbital electron is "absorbed" by the nucleus. The end effect on nuclear structure is the same; a proton appears to have changed into a neutron, the atomic number decreases by one, and the atomic mass remains the same. For example, ^{125}I decays exclusively by electron capture to tellurium-125 ($^{125}_{53}I \rightarrow {}^{125}_{52}Te$).

Gamma Radiation and Internal Conversion. The original observations of naturally occurring radioactive nuclides disclosed a third radiation, the *gamma* (γ-) *ray.* Its ability to penetrate materials that blocked γ- and β-radiation distinguished this radiation. Gamma radiation is high-energy electromagnetic radiation that resemble x-rays. An example of a γ-emitter is ^{131}I. Gamma radiation may accompany either α- or β-particle emission. After either α- or β-decay or after electron capture, the nucleus may be left in an excited state from which it goes to the ground state by shedding the excess energy either through the emission of a γ-photon or through the ejection of an orbital electron *(conversion electron).* In either case the energy emitted equals the energy released in deexcitation. Deexcitation may occur in one or in multiple steps. Each step produces a photon of corresponding energy. For every radionuclide, the deexcitation steps and the corresponding γ-ray energies provide a unique γ-*ray spectrum,* which can be used to identify unknown nuclides. Because γ-rays are high-energy photons, they interact with matter much less strongly than do α- and β-particles and consequently their penetrating power is very high and more difficult to shield.

Activity and Half-life

The rate of decay of a radioactive source is called its *activity* and is simply the rate at which radioactive parent atoms decay to more stable daughter atoms. The relationship between the initial activity (A_0) at time zero and the activity (A) after an elapsed time t, is given by:

$$A = -\frac{dN}{dt} = A_0 e^{-\lambda t}$$

where N is the number of atoms present at time t and λ is the decay constant characteristic of a given nuclide.

In practice, it is often convenient to describe the rate of decay in terms of *half-life* ($t_{1/2}$), the time required for a nuclide's e activity to decrease to half its initial value:

$$t_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda}$$

This equation is useful in planning experiments and in the disposal of radioactive waste. For disposal, a rule of thumb is that a decay time of seven half-lives reduces the activity to less than 1% of its original value (2^{-7} = 1/128 = 0.78%), and that after 10 half-lives, to less than 0.1%.

Units of Radioactivity

The *becquerel* (Bq) is the SI unit of radioactivity and is defined as one decay per second (dps). Because 1 Bq is a very small amount of activity, the activity of typical chemistry samples is often expressed in kilobecquerels (kBq). The *curie* (Ci) is the older, *conventional unit;* it is defined as 3.7×10^{10} dps. One curie equals 37 gigabecquerels (GBq). Because the becquerel is inconveniently small and the curie very large, they are typically used as their multiples or submultiples, for example, megabecquerels (MBq) and millicuries (mCi). One mCi equals 37 MBq.

Specific Activity

The term "specific activity" has several meanings. It may refer to any one of the following: radioactivity per unit mass of an element, radioactivity per mass of labeled compound, or radioactivity per unit volume of a solution. The denominator of reference must be specified. In terms of radioactivity per unit mass, the maximum specific activity attainable for each radionuclide is that for the pure radionuclide. For example, pure ^{14}C has a specific activity of 62 Ci/mol or 4400 Ci/kg. As usually available, ^{14}C is a tracer for compounds in which it represents only a small fraction of the total carbon, most of which is the naturally occurring mixture of stable ^{12}C and stable ^{13}C. If there is no stable element present, the radionuclide is said to be *carrier free.*

Detection and Measurement of Radioactivity

Autoradiography, gas ionization detectors, and fluorescent scintillation are the basis for techniques used to detect and measure radioactivity in the clinical laboratory.

Autoradiography

In autoradiography a photographic emulsion is used to visualize molecules labeled with a radioactive element. For example, this technique is used to visualize nucleic acids and fragments that have been hybridized with nucleic acid probes labeled with ^{32}P (see Chapter 37). With such techniques, nucleic acid probes labeled with radioactive ^{32}P are incubated with target nucleic acid. After hybridization, hydrolysis, and separation of fragments by gel electrophoresis, a photographic film is applied to the covered gel and allowed to incubate. Alternatively the nucleic acid fragments are transferred to a nylon membrane and the photographic film applied to the membrane (see Chapter 5). With either, the film is developed with the resulting image reflecting the radioactivity of the target nucleic acid fragments.

Gas-Filled Detectors

Detectors filled with certain gases or gas mixtures are designed to capture and measure the ions produced by radiation within the detector. Gas-filled detectors used to measure radioactivity include the: (1) *ionization chamber*, (2) *proportional counter*, and (3) *Geiger counter*. Of the three, the Geiger counter is used in the clinical chemistry laboratory as a portable radiation monitor.

Scintillation Counting

In both scintillator and gas detectors, the absorption of radiation causes excitation and ionization; however with the scintillation process, the absorbed energy produces a flash of light, rather than a pulse of current. The principal types of scintillation detectors found in the clinical chemistry laboratory are the sodium iodide *crystal scintillation detector* and the *organic liquid scintillation detector*. Because of the crystal detector's relative ease of operation and economy of sample preparation, most clinical laboratory procedures have been developed to measure nuclides, such as ^{125}I, which can be counted efficiently in a crystal detector. A liquid scintillation detector is used to measure pure β-emitters, such as tritium or ^{14}C.

Crystal Scintillation Detector. The *well detector* is a common type of a crystal scintillation detector and has a hole drilled in the end or side of the cylindrical crystal to accept a test tube. Because it is hygroscopic, the crystal is hermetically sealed in an aluminum can with a transparent quartz window at one end through which the blue-violet (420 nm) scintillations are detected. The photons of gamma emitters, such as ^{51}Cr, ^{57}Co, ^{59}Fe, ^{125}I, and ^{131}I (Table 1-14) in the sample easily penetrate the specimen tube and the thin, low-density can and enter the crystal where they are likely to be absorbed in the thick, high-density sodium iodide. A well counter is not suitable for measuring β-radiation, because it cannot penetrate the sample container and aluminum lining of the wall.

The crystal itself is usually a circular cylinder machined from a single crystal of sodium iodide that was carefully grown to ensure optical clarity for efficient light collection. A small amount of thallium is added to the mother liquor to improve performance. The high atomic number of iodine and the density of sodium iodide ($3.7\,g/cm^3$) favor the absorption of γ-radiation. For this reason, a well counter is often referred to as a γ-counter. For a typical well detector, the counting efficiency for ^{125}I, expressed as the percentage of decays that produces counts, approximates 70%.

Liquid Scintillation Detector. This detector measures radioactivity by recording scintillations occurring within a transparent vial that contains the unknown sample and liquid scintillator. Because the radionuclide is intimately mixed with, or actually dissolved in, the liquid scintillator, the technique is ideal for the pure β-emitters, such as ^{3}H, ^{14}C, and ^{32}P. Typical efficiencies for liquid scintillation counting in the absence of significant quenching are 60% for tritium and 90% for ^{14}C.

The liquid scintillator is known as the *scintillation cocktail* and contains at least two components (the primary solvent and the primary scintillator). The *primary solvent* is usually inexpensive and chosen for its efficiency in absorbing and transferring radiation energy. It is usually one of the aromatic hydrocarbons: toluene, xylene, or pseudocumene (1,2,4-trimethyl benzene). The *primary scintillator* absorbs energy from the primary solvent and converts it into light. The usual material is PPO (2,5-diphenyl oxazole) used in a concentration of 3 to 6 g/L. PPO emits ultraviolet light of 380 nm. In addition, other components added to the liquid scintillator include: (1) a *secondary solvent* to improve the solubility of aqueous samples, (2) a surfactant to stabilize or emulsify the sample, (3) a *secondary scintillator*, sometimes referred to as a wavelength shifter, to absorb the ultraviolet photons of the primary scintillator and reemit the energy at a longer wavelength, which facilitates the response of some photomultiplier tubes, and (4) one or more *adjuvants*, such as suspension agents, solubilizers for biological tissue, and antifreezes, to prevent freezing and separation of water at low temperatures.

Other Components and Techniques. Other components of a liquid scintillator detector include: (1) electronics, (2) a photomultiplier tube, (3) a preamplifier, and (4) a pulse-height analyzer. Description of these components and discussion of relevant topics such as (1) efficiency of scintillation counting, (2) quenching, (3) counting statistics, (4) assay optimization, and (5) radiation safety can be found in an earlier edition of this textbook.[46]

Gravimetry

Mass is an invariant property of matter. Gravimetry is the process used to measure the mass of a substance. Weight is

a function of mass under the influence of gravity, a relationship expressed by the equation:

$$\text{Weight} = \text{mass} \times \text{gravity}$$

Two substances of equal weight and subject to the same gravitational force have equal masses. The determination of mass is made using a balance to compare the mass of an unknown with that of a known mass. This comparison is called *weighing*, and the absolute standards with which masses are compared are called *weights*. In practice, the terms *mass* and *weight* are used synonymously.

The classic form of a balance is a beam poised on an agate knife-edge fulcrum, with a pan hanging from each end of the beam and a rigid pointer hanging from the beam at the poise point. With the object to be weighed on one pan and weights of equal mass on the other pan, the pointer comes to rest at an equilibrium or balance point between the extremes of the path of excursion. The weight required to achieve the equilibrium is therefore equal to the weight of the substance being weighed.

Although the classic form of the balance is of great antiquity, modern balances—both mechanical and electronic—continue to apply the principle of equilibrium in a variety of ingenious ways. More than one type of balance is required for a clinical laboratory because there is a necessity to weigh, for example, 3 kg of timed urine output and microgram amounts of drug for a reference solution. Coarse balances of large capacity (up to 5 kg) have a detection limit of 0.1 g. The typical analytical balance has a capacity of 200 g and a detection limit of about 10 µg. Microbalances may have a maximum capacity of as little as 5 g and detection limit of 0.1 µg.

All balances require a vibration-free location. The more sensitive a balance, the more protection it requires, not only from vibration but also from air currents that can disturb the equilibrium between the weighed object and weights. The zero or null point of the balance (the rest point in the absence of either weights or an object to be weighed) must be known or kept adjusted. Scrupulous attention to cleanliness is essential. Chemical substances being weighed should never be placed in direct contact with the pans. Disposable plastic weighing boats come in various sizes and are convenient for weighing most chemicals. They have largely replaced weighing bottles and weighing paper for most uses. Loose crystals of chemicals or liquids with corrosive vapors should not be permitted to remain on or around the immediate area of the pans. Good weighing technique for samples weighing less than 1 g calls for handling weights with forceps and weighed objects with suitable utensils to prevent deposition of moisture, oils, or salts from an analyst's skin.

Principles of Weighing

Direct comparison and substitution are the two operations used in weighing. In weighing by *direct comparison*, weights are added to one side of the beam to counterbalance the weight of the object on the other side. This approach is more common. In weighing by *substitution*, weights are removed from the side of a balance to which the object to be weighed has been added to restore equilibrium.

In practice, two modes of weighing are used: (1) analytical weights are added to equal the weight of the object being weighed or (2) the material to be weighed is added to a balance pan to achieve equilibrium with a preset weight. This second mode is used more commonly in clinical laboratories, where the major necessity is to weigh a fixed quantity of chemical so that a calibrator or reagent solution of known concentration may be prepared. Before weighing a sample of the chemical, the weight of the container must be determined to subsequently allow for deducting the weight of the container from the gross weight of the container plus sample to obtain the net weight of the sample: a process called "taring." When taring is impractical, the weight of the empty container must be subtracted from the combined weight of the container and the material to obtain the weight of the material alone.

Types of Balances

Double- and single-pan and electronic balances are frequently used in the clinical laboratory.

Double-Pan Balance

A double-pan balance conforms to the classic design, consisting of a single beam with arms of equal length. Standard weights are usually added by hand to the right-side pan to counterbalance the weight of the object on the other, but in some models, a dial or vernier with chain is used to make fine adjustments to the mass associated with the right-side pan. In *single-pan* balances, the arms are of unequal length. The object to be weighed is placed on the pan attached to the shorter arm. A restoring force is applied mechanically or electronically to the other arm to return the beam to its null position. Double- and triple-beam balances are forms of the unequal-arm balance. A single pan on a short arm is balanced about a fulcrum by a larger arm consisting of two or three parallel beams to which weights or poises of different weights are attached. In general these balances are designed to weigh bulk reagents and have relatively low accuracy.

Single-Pan Balance

The single-pan balance is a commonly used balance in the clinical laboratory. It is most often electronically operated and self-balancing. Such a balance may be coupled directly to a computer or recording device. In the electronic single-pan balance, a load on the pan causes the beam to tilt downward. A null detector senses the position of the beam and indicates when the beam has deviated from the equilibrium point.

Electronic Balance

In an electronic balance, an electromagnetic force is applied to return the balance beam to its null position. The electro-

magnetic force takes the place of weights in a two-pan balance. The restoring force is proportional to the weight on the pan and is applied through a solenoid or torque motor. The current required to produce the force is displayed digitally by liquid crystals or light-emitting diodes in a form equivalent to the mass on the balance pan. The accuracy of an electronic balance depends on the linearity of both the digital voltmeter and the torque motor. Almost all electronic balances have a built-in provision for taring so that the mass of the container is subtracted easily from the total mass measured. Thus operation of an electronic balance is very simple. It entails switching on the balance, placing a container to hold the material to be weighed on the balance pan, taring off the weight of the container, transferring the material to be weighed to the container, and recording the mass of the material as shown on the digital display. In many modern balances, a built-in microprocessor compensates for changes in temperature and provides both automatic zero tracking and calibration.

Analytical Weights

Analytical weights are used to counterbalance the weight of objects weighed on two-pan balances and to verify the performance of both single- and two-pan balances. The NIST recognizes the following five classes of analytical weights:

1. Class M weights are of primary standard quality and are used only to calibrate other weights.
2. Class S weights are used for calibrating balances. In the clinical laboratory, balances should be calibrated at least monthly and before conducting very accurate analytical work.
3. Class S-1 weights have greater tolerance than class S weights and are used for routine analytical work.
4. Class P weights have even tighter tolerances.
5. Class J weights are intended for microanalytical work and range from 0.05 to 50 mg, in contrast to the range of 1 mg to 100 g of the other classes.

Class S weights are typically made from brass or stainless steel and are lacquered or plated for protection. The fractional weights of a set of class S standards are usually made of platinum or aluminum. Tolerances of the different weights have been defined by the NIST. For class S weights from 1 to 5 g, the tolerance is ± 0.054 mg, from 500 to 100 mg it is ± 0.025 mg, and from 1 to 50 mg it is ± 0.014 mg.

Thermometry

In the clinical chemistry laboratory, measurements of temperature are made primarily to verify that devices measure within the prescribed temperature limits. Water baths or heated cells where reactions take place are examples of such devices, as are refrigerators, whose temperatures must be measured and recorded daily to meet laboratory regulatory requirements.

The two most popular types of thermometers in the chemistry laboratory are liquid-in-glass thermometers and thermistor probes. A thermistor made of a transition metal oxide whose resistance changes with temperature is the most common of the latter type.

All thermometers must be verified against a certified thermometer before being placed into use. For example, the NIST SRM 934 is a mercury-in-glass thermometer with calibration points at 0 °C, 25 °C, 30 °C, and 37 °C. Some manufacturers supply liquid-in-glass thermometers that have ranges greater than the SRM thermometer and are verified to have been calibrated against the NIST thermometers. Details of the verification of the calibration of a thermometer have been described in a NCCLS standard.[26]

The NIST also supplies several materials that melt at a known temperature. For example, gallium (SRM 1968) and rubidium (SRM 1969), which melt at 29.7723 °C and 39.3 °C, respectively, are particularly useful in the clinical laboratory (see Table 1-10).

Buffer Solutions

Buffers are defined as substances that resist changes in the pH of a system. All weak acids or bases, in the presence of their salts, form buffer systems. The action of buffers and their role in maintaining the pH of a solution can best be explained with the aid of the Henderson-Hasselbalch equation, which may be derived as follows.

The ionization of a weak acid, HA, and of a salt of that acid, BA, can be represented as:

$$HA \rightleftharpoons H^+ + A^-$$

$$BA \longrightarrow B^+ + A^-$$

The dissociation constant for a weak acid (K_a) may be calculated from the following equation:

$$K_a = \frac{[H^+][A^-]}{[HA]}$$

Thus

$$[H^+] = K_a \times \frac{[HA]}{[A^-]}$$

or

$$\log[H^+] = \log K_a + \log\frac{[HA]}{[A^-]}$$

where brackets indicate the concentration of the compound contained within. Now multiplying throughout by –1:

$$-\log[H^+] = -\log K_a - \log\frac{[HA]}{[A^-]}$$

By definition, pH = –log [H^+], and pK_a = –log K_a, therefore

$$pH = pK_a + \log\frac{[A^-]}{[HA]}$$

Because A^- is derived principally from the salt, the equation may, for practical purposes, be written:

$$pH = pK_a + \log\frac{[salt]}{[undissociated\ acid]}$$

or simply:

$$pH = pK_a + \log\frac{[salt]}{[acid]}$$

where [salt] = [A^-] = concentration of dissociated salt and [acid] = [HA] = concentration of undissociated acid.

Consequently, the pH of the system is determined by the pK_a of the acid and the ratio of [A^-] to [HA]. The buffer has its greatest buffer capacity at its pK_a, that is, that pH at which the [A^-] = [HA]. This entered into the preceding equation gives:

$$pH = pK_a + \log 1$$
$$pH = pK_a + 0$$

The capacity of the buffer decreases as the ratio deviates from 1. In general buffers should not be used at a pH greater than 1 unit from their pK_a. If the ratio is beyond 50/1 or 1/50, the system is considered to have lost its buffering capacity. This point is approximately 1.7 pH units to either side of the pK_a of the acid, because

$$pH = pK_a + \log\frac{50}{1} + \log\frac{1}{50}$$

or

$$pH = pK_a \pm 1.7$$

Buffers commonly used in clinical and molecular diagnostic laboratories include acetate, boric acid–borate, carbonate-bicarbonate, citrate diethanolamine, glycine-glycinate, phosphate, phthalate, tris(hydroxymethyl) aminomethane, and veronal–sodium veronal, and the so-called "Good" buffers (Table 1-15).

Procedures for Processing Solutions

Several procedures are routinely used to process solutions in the clinical laboratory, including those for diluting, concentrating, and filtering solutions.

TABLE 1-15 Biological Buffers Commonly Used in the Laboratory*

Trivial Name	Chemical Name	pK_a†	Useful pH Range
ACES	N-(2-Acetamido)-2-aminoethane-sulfonic acid	6.8	6.1-7.5
ADA	N-(2-Acetamido)iminodiacetic acid	6.6	6.0-7.2
AMP	2-Amino-2-methyl-propanol	9.7	9.0-10.5
AMPSO	3-([1,1-Dimethyl-2-hydroxyethyl]amino)-2-hydroxypropanesulfonic acid	9.0	8.3-9.7
BES	N,N-Bis(2-hydroxyethyl)-2-aminoethane sulfonic acid	7.1	6.4-7.8
BICINE	N,N′-Bis(2-hydroxyethyl)glycine	8.3	7.6-9.0
BIS-TRIS	2-(Bis[2-hydroxyethyl]amino)-2-(hydroxymethyl)-1,3-propanediol	6.5	5.8-7.2
BIS-TRIS PROPANE	1,3-Bis(tris[hydroxymethyl]methylamino)propane	6.8 & 9.0	6.3-9.0
CAPS	3-(Cyclohexylamino)propane sulfonic acid	10.4	9.7-11.1
CAPSO	3-(Cyclohexylamino)-2-hydroxy-1-propanesulfonic acid	9.6	8.9-10.3
CHES	2-(Cyclohexylamino)ethane-2-sulfonic acid	9.3	8.6-10.0
DIPSO	N,N-Bis(2-hydroxyethyl)-3-amino-2-hydroxypropanesulfonic acid	7.6	7.0-8.2
EPPS/HEPPS	N-(2-Hydroxyethyl)piperazine-N′-(3-propanesulfonic acid)	8.0	7.3-8.7
HEPBS	N-(2-Hydroxyethyl)piperazine-N′-(4-butanesulfonic acid)	8.3	7.6-9.0
HEPES	N-(2-Hydroxyethyl)piperazine-N′-2-ethanesulfonic acid	7.5	6.8-8.2
HEPPSO	N-(2-Hydroxyethyl)piperazine-N′-3-propanesulfonic acid	7.8	7.1-8.5
MES	Morpholinoethane sulfonic acid	6.1	5.5-6.7
MOBS	4-(N-Morpholino)butane sulfonic acid	7.6	6.9-8.3
MOPS	Morpholinopropane sulfonic acid	7.2	6.5-7.9
PIPES	Piperazine-N,N′-bis(2-ethane sulfonic acid)	6.8	6.1-7.5
POPSO	Piperazine-N,N′-bis(2-hydroxypropanesulfonic acid)	7.8	7.2-8.5
TABS	N-tris(Hydroxymethyl)methyl-4-aminobutanesulfonic acid	8.9	8.2-9.6
TAPS	N-Tris(hydroxymethyl)methyl-3-aminopropane sulfonic acid	8.4	7.7-9.1
TES	N-Tris(hydroxymethyl)methyl-2-aminoethane sulfonic acid	7.5	6.8-8.2
TRICINE	N-Tris(hydroxymethyl)methylglycine	8.1	7.4-8.8
TRIS	2-Amino-2-(hydroxymethyl)-1,3-propane	8.1	7-9

*These buffers are known collectively as "Good" buffers. (Good NE, Winget GD, Winter W, et al, Hydrogen ions buffers for biological research. Biochemistry 1966; 5:467-77.)

†Data obtained at 25 °C.

Dilution

Dilution is the process whereby the concentration or activity of a given solution is decreased by the addition of solvent. In laboratory practice, most dilutions are made by transferring an exact volume of a concentrated solution into an appropriate flask and then adding water or other diluent to the required volume, with appropriate mixing to ensure homogeneity. A serial dilution is a sequential set of dilutions in mathematical sequence. A given dilution is expressed as the amount, either volume or weight, of a solute (analyte) in a specified volume. For example, a 1:5 volume to volume (vol/vol) dilution contains one volume in a total of five volumes (one volume plus four volumes).

To prevent errors that arise when two liquids of very different composition are mixed, the technique of diluting to volume is used. Instead of adding 90 mL water to 10 mL concentrated solution, the 10-mL concentrated solution should be pipetted into a 100-mL volumetric flask, and water is added to bring the volume to the 100-mL mark on the neck of the flask.

When performing a dilution, the following equation is used to determine the volume (V_2) necessary to dilute a given volume (V_1) of solution of a known concentration (C_1) to the desired lesser concentration (C_2):

$$C_1 \times V_1 = C_2 \times V_2$$

or

$$V_2 = \frac{C_1 \times V_1}{C_2}$$

Likewise, the equation is also used to calculate the concentration of the diluted solution when a given volume is added to the starting solution.

Evaporation

Evaporation is a process used to convert a liquid or a volatile solid into vapor. It is used in the clinical laboratory to remove liquid from a sample thereby increasing the concentrations of analyte(s) left behind.

Lyophilization

Lyophilization (freeze drying) is used in laboratory medicine for the preparation of calibrators, control materials, reagents, and to a lesser extent individual specimens for analysis. Lyophilization first entails freezing a material at −40 °C or less and then subjecting it to a high vacuum. Very low temperatures cause the ice to sublime; solid nonsublimable material, initially locked in an ice matrix, remains behind in a dried state.

Filtration

Filtration is defined as the passage of a liquid through a filter and is accomplished by gravity, pressure, or vacuum. *Filtrate* is the liquid that has passed through the filter. The purpose of filtration is to remove particulate matter from the liquid. Many filtrations in the clinical laboratory are carried out with *filter paper* and with plastic *membranes* of controlled pore size.

Membrane filters are used under vacuum, with positive pressure, or with gravity. Filters have been incorporated into certain disposable tips for use with semiautomatic pipettes. These filters minimize the exchange of aerosol droplets between the tips and the pipette. This is of particular importance for DNA amplification and microbiological procedures. Other membrane filters are designed for ultrafiltration and are available with a variety of pore sizes for selective filtration. *Ultrafiltration* is a technique for removing dissolved particles using an extremely fine filter. It is used to concentrate macromolecules, such as proteins, because smaller dissolved molecules pass through the filter.

SAFETY

In the United States, the Federal Occupational Safety and Health Act of 1970 was the beginning of the formal regulatory oversight of employee safety. Since 1970 the Occupational Safety and Health Administration (OSHA) and the Centers for Disease Control and Prevention (CDC) have published numerous safety standards that apply to clinical laboratories. Each year as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and the College of American Pathologists (CAP) revise their guidelines, more attention is devoted to safety. Consideration for the health and responsibility for the safety of employees are now accepted as obligations of all employers and laboratory directors. In May of 1988, OSHA expanded the Hazard Communication Standard to apply to hospital workers. Part of this standard is frequently referred to as the "Lab Right to Know Standard."

There are many aspects to the safe operation of a clinical laboratory. Key elements for safety in the clinical laboratory include:

1. A formal safety program
2. Documented policies and effective use of mandated plans and/or programs in the areas of chemical hygiene, control of exposure to blood-borne pathogens, tuberculosis control, and ergonomics
3. Identification of significant occupational hazards, such as biological, chemical, fire, and electrical hazards and clearly identifying and documenting policies for employees to deal with each type of hazard (e.g., packaging and shipping of diagnostic specimens and infectious substances)
4. Recognition that in the twenty-first century clinical laboratory, there are additional important and relevant safety areas of concern. These areas include effective waste management policies for the identification and disposal of regulated and nonregulated waste streams with the intent of ensuring compliance with all federal and state agency mandates, and bioterrorism and chemical terrorism response plans in the event of potential threats or casualties involving these types of agents.

Safety Program

Every clinical laboratory must have a comprehensive and effective formal safety program. Regardless of the size of the clinical laboratory, it is an accepted and strongly recommended practice to assign a specific individual the title of "Safety Officer" or "Chair of the Safety Committee." Safety is each employee's responsibility, but responsibility for the entire program begins with the laboratory leadership (directors, administrative directors, supervisors, managers, etc.) and is delegated through the leadership to the safety officer or safety committee. This individual or committee then has the duties of providing guidance to laboratory leadership on matters relating to the provision of a safe workplace for all employees. The duties and responsibilities of the safety officer and/or safety committee are important. Although a small institution may have one individual who deals with all safety-related matters for all departments including the laboratory, OSHA[41] mandates that the laboratory specifically have a chemical hygiene officer who is designated based on training or experience to provide technical guidance in the development of the chemical hygiene plan (CHP) discussed later.

An integral part of the laboratory safety program is the education and motivation of all laboratory employees in all matters relating to safety. Each new employee should be given a copy of the general laboratory safety manual as part of his or her orientation. Each employee should know the location of available fire-fighting equipment and how to use it and where the evacuation routes are. The continuing education program of the laboratory should include periodic talks on safety. Several audiovisual resources are available from a variety of sources to support the continuing educational part of the safety program. These include videotapes adapted from selected NCCLS documents relating to laboratory safety.[27,32]

Another important part of the laboratory safety program relates to ensuring that the laboratory environment meets accepted safety standards. This effort would include, but not be limited to, attention to such items as proper labeling of chemicals, types and location of fire extinguishers, hoods that are in good working order, proper grounding of electrical equipment, ergonomic issues (which include equipment, such as pipetting devices, laboratory furniture, and prevention of musculoskeletal disorders) and providing means for the proper handling and disposal of biohazardous materials, including all patient specimens. As noted previously, effective waste management is a key aspect of laboratory safety. NCCLS has an approved guideline that deals in detail with management of clinical laboratory waste.[28]

Provision of all required safety equipment, regularly scheduled employee training sessions (including relevant documentation and certification, if necessary, such as with the federally mandated packaging and shipping regulations for infectious specimens), and scheduling of periodic inspections are all necessary activities to ensure that the laboratory staff is complying with the various mandates of the safety program.

Safety Equipment

A large and growing number of safety items are available for employees of the laboratory. OSHA requires that institutions provide employees with all necessary personal protective equipment (PPE). Many safety items are shown and described in a Safety Products Reference Manual.[51] Key important safety items are clothing (such as laboratory coats, gowns, and/or scrubs), gloves, and eye protection. These safety items should be used in areas where they are appropriate. Eye washers or face washers should be available in every chemistry laboratory. Many types are available, and some simply connect to existing plumbing. A hand-held eye and/or face safety spray is a requisite safety device and can be consistently placed in a position next to each sink while using only a few inches of space. Safety showers, strategically located in the laboratory, must be available and should be tested on a regular schedule.

Heat-resistant (nonasbestos) gloves should be available for handling hot glassware and dry ice. Safety goggles, glasses, and visors, including some that will fit conveniently over regular eyeglasses, are available in many sizes and shapes. Personnel wearing contact lenses should be aware of the danger of irritants getting under a lens; wearing such lenses can make it difficult to irrigate the eye properly. Shatterproof safety shields should be used in front of systems posing a potential danger because of implosion (vacuum collapse) or pressure explosions. Desiccator guards should be used with vacuum desiccators. Hot beakers should be handled with tongs. Inexpensive polyethylene pumps are available to pump acids from large bottles. Spill kits for acids, caustic materials, or flammable solvents come in various sizes. Such kits and the other appropriate safety materials should be located in convenient and appropriate sites in the laboratory.

A chemical fume hood is a necessity for every clinical chemistry laboratory. The fume hood is the only safe place to open any container of a material that gives off harmful vapors, to prepare reagents that produce fumes, and to heat flammable solvents. In the event of an explosion or fire in the hood, closing its window contains the fire.

Safety Inspections

It is good laboratory practice to organize a safety inspection team from the laboratory staff. This team is then responsible for conducting periodic and scheduled safety inspections of the laboratory.[32]

In the United States there are several regulatory, private accreditation, state, and federal organizations that may conduct a safety inspection of the laboratory. Some of these safety inspections may occur unannounced. From an external perspective, OSHA inspectors have the authority to enter a clinical laboratory unannounced and, on presentation of credentials, inspect it. The inspection may be regular or as a result of a complaint. In addition, the Commission on Inspection and Accreditation of the CAP inspects clini-

cal laboratories and uses various safety checklists (available to the laboratory before inspection) when evaluating a laboratory for accreditation. These inspections are carried out on a regular basis. Although the JCAHO will accept CAP accreditation of a laboratory, it may still conduct a safety inspection of the laboratory when it inspects the hospital. The JCAHO is also planning to conduct their accreditation inspections, which may include a full laboratory or laboratory safety component, unannounced.

Depending on the group designated responsible for accrediting a particular laboratory, selected laboratories may be subject to inspections for the purposes of accreditation and/or safety only by state agencies or local Center for Medicare and Medicaid Services (CMS) groups. Inspections may also be made on a regular basis by state or local health departments or by local fire departments to determine conformance to their particular safety requirements. Currently a laboratory that meets federal or state OSHA requirements is likely to satisfy the standards of any other inspecting agency.

Mandated Plans

In 1991 OSHA mandated that all clinical laboratories in the United States must have a chemical hygiene plan (CHP)[41] and an exposure control plan.[42] OSHA has since updated their requirements for the exposure control plan to provide new examples of engineering controls and to place significantly greater responsibilities on employers to minimize and manage employee occupational exposure to blood-borne pathogens.[43] The CAP and other groups require that an accredited laboratory must have a documented tuberculosis exposure control plan conforming with biosafety guidelines published by the CDC.[5,17] There has been a resurgent recognition that the workplace setting of a clinical laboratory does expose employees to the occupational risk of having various musculoskeletal disorders. As a result, the focus of OSHA on laboratories having an effective ergonomics program has led to federal, state, and private accreditation groups addressing this area of occupational safety. Unfortunately, there has been considerable controversy in implementing a final ergonomics rule as one was published in 2001 and then withdrawn.[11,44]

Chemical Hygiene Plan

Major elements of a CHP plan include listing of responsibilities for employers, employees, and a chemical hygiene officer. Also among the items that have to be covered in the plan is the stipulation that every laboratory must have a complete chemical inventory that is updated annually. A copy of the Material Safety Data Sheet (MSDS), which defines each chemical as toxic, carcinogenic, or dangerous, must be on file and readily accessible and available to all employees 24 hours a day, 7 days a week. The MSDS contains important information for the benefit of laboratory employees. The chemical manufacturer's information as supplied on the MSDS is used to ascertain whether a certain chemical is hazardous. Each MSDS must give the product's identity as it appears on the container label and the chemical and common names of its hazardous components. The MSDS also provides physical data on the product, such as boiling point, vapor pressure, and specific gravity. Easily recognized characteristics of the chemical are also listed on the line for "appearance and odor." Information about hazardous properties is given in detail on the MSDS; this includes fire and explosion hazard data and health-related data, including the threshold limit value (TLV), exposure limits, and toxicity values. The TLV is the exposure allowable for an employee during one 8-hour day. It also notes effects of overexposure and provides first-aid procedures. Each MSDS also provides information on spill and disposal procedures and protective personal gear and equipment requirements. Originally there was no standard format for MSDSs, which made information hard to find. In June 1993 the American Standards Institute (ANSI) approved a new standard that specified a standard format for MSDSs.[53]

Exposure Control Plan

OSHA regulations[42,43] require that each laboratory develop, implement, and adhere to a plan that ensures the protection of laboratory workers against potential exposure to blood-borne pathogens[27,32,42] and to ensure that the medical wastes produced by the laboratory are managed and handled in a safe and effective manner.[28,32] OSHA regulations also place responsibility on employers for implementing new developments in exposure control technology; to solicit the input of employees directly involved in patient care in the identification, evaluation, and selection of these work practice controls; and in certain instances to maintain a log for employee percutaneous injuries from sharp devices, such as syringe needles.[43] Organizationally the plan should include sections on (1) purpose, (2) scope, (3) applicable references, (4) applicable definitions, (5) definition of responsibilities, and (6) detailed procedural steps.

When implementing the plan, each laboratory employee must be placed into one of three groups. The three classifications are as follows:

Group I: A job classification in which **ALL** employees have occupational exposure to blood or other potentially infectious materials.

Group II: A job classification in which **SOME** employees have occupational exposure to blood or other potentially infectious materials. Employees in this group would be those whose performance of their duties as defined by their job classification, or whose special assigned tasks, put them at risk for *possible* exposure to human blood or other potentially infectious materials. An example of an employee who would fit into this classification would be an instrument technician whose duties require routine maintenance or repair of an instrument in which blood or other potentially infectious materials might be encountered. These individuals must receive the same training and orientation as employees in Group I.

Group III: A job classification in which employees do **NOT** have **ANY** occupational exposure to blood or other potentially infectious materials. It is not mandatory that employees who qualify in this group receive training on the OSHA Bloodborne Standard. It is imperative, however, that these employees are never asked to perform any procedure that would subject them to occupational exposure. If at any future date an employee in this group has any additional duties added to his or her job that would include any exposure-prone tasks, then this employee needs to be added to the Group II list. Training of this employee in all aspects of the OSHA Bloodborne Standard **MUST** be completed before his or her actual performance of these new duties. In addition, this employee must be offered vaccination for hepatitis B within 10 working days of initial assignment to a position involving exposure.

Tuberculosis Control Plan[17]

The purpose of the tuberculosis control plan is to prevent the transmission of tuberculosis (TB), which occurs when an individual inhales a droplet that contains *Mycobacterium tuberculosis. M. tuberculosis* is aerosolized when an infected individual sneezes, speaks, or coughs. Transmission of TB and exposure to TB can be greatly diminished with early identification and isolation of patients at risk, environmental controls, appropriate use of respiratory protection equipment, education of laboratory employees, and when necessary early initiation of therapy.

An effective tuberculosis control plan will include determination of exposure at regular intervals for all employees who are at occupational risk. Engineering and work practice controls are particularly important in laboratory areas, such as surgical pathology and microbiology. But there is clearly a risk of exposure from specimens of patients with suspected or confirmed tuberculosis in every section of the laboratory, including chemistry.

Ergonomics Program

More than one third of occupational related injuries or illnesses reported by employees to the U.S. Bureau of Labor Statistics are estimated to be caused by musculoskeletal disorders. In 2003 federal regulations based on occupational management guidelines that are 15 years old are still not finalized as a result of OSHA continuing to work with Congress and small business advocacy groups to complete a rule that is deemed fair to both employees and employers.[11,37,44]

There are several areas of occupational risk for development of musculoskeletal disorders in the clinical laboratory.[36] These include routine laboratory activity, functionality of the workspace (including laboratory floor matting, bright lighting, and noise generation), and equipment design (computer keyboards and displays, workstations, and chairs). One particular laboratory function, pipetting and related pipette design, has received considerable attention. As depicted in Figure 1-2, pipettes are being designed with a goal of reducing an employee's risk of having cumulative stress disorders caused by awkward posture, repetitive motion, and the repeated use of force. An example of an ergonomically engineered laboratory work chair is shown in Figure 1-5.

The CAP requires accredited laboratories to have a comprehensive and defined ergonomics program that is designed to prevent work-related musculoskeletal disorders through prevention and engineering controls. The documented ergonomics plan should include elements of employee training regarding the areas of risk, engineering controls to minimize or eliminate risks, and an assessment process to identify problematic issues for documentation and remediation.[14]

Hazards in the Laboratory

Various types of hazards are encountered in the operation of a clinical laboratory. These hazards must be identified and labeled, and work practices developed for dealing with them. The major categories of hazards encountered include biological, chemical, electrical, and fire hazards.

Identification of Hazards

Clinical laboratories deal with each of the nine classes of hazardous materials. These are classified by the United Nations (UN) as (1) explosives, (2) compressed gases,[8] (3) flammable liquids, (4) flammable solids, (5) oxidizer materials, (6) toxic materials, (7) radioactive materials, (8) corrosive materials, and (9) miscellaneous materials not elsewhere classified. Shipping and handling of Class (6) toxic materials,

Figure 1-5 A example of an ergonomically designed laboratory chair. *(Courtesy MarketLab Inc.)*

specifically biological and potentially infectious materials, has received considerable attention. In 2002 the U.S. Department of Transportation (DOT) released a revised rule with standards for infectious substance hazardous material handling.[3,20] The impact and requirements of these regulations are described in the section on biological hazards.

Warning labels aid in the identification of chemical hazards during shipment. Under regulations of the DOT, chemicals that are transported in the United States must carry labels based on the UN classification. DOT placards or labels are diamond shaped with a digit imprinted on the bottom corner that identifies the UN hazard class (1 to 9). The hazard is identified more specifically in printed words placed along the horizontal axis of the diamond. Color coding and a pictorial art description of the hazard supplement the identification of hazardous material on the label; the artwork appears in the top corner of the diamond (Figure 1-6, *A*).

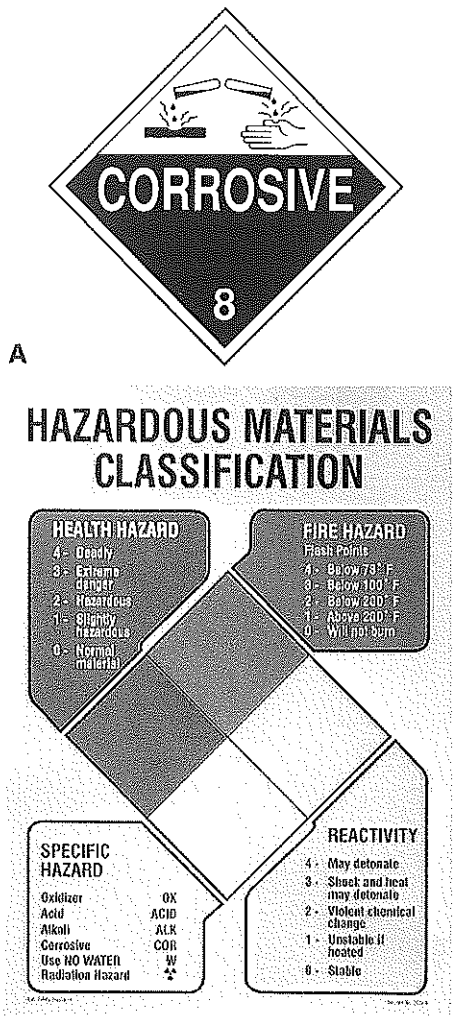

Figure 1-6 A, Department of Transportation label for corrosives. **B,** Labeling identification system of the National Fire Protection Association. *(Courtesy Lab Safety Supply Inc., Janesville, Wis.)*

The upper half of the label for corrosive materials shows a metallic bar and a hand, both of which are being eaten away by drops of fluid; the black bottom half of the label is lettered "corrosive" in white. The bottom corner shows the digit "8."

The system is used by the DOT for shipping hazardous materials; however, when the hazardous material reaches its destination and is removed from the shipping container, this identification is lost. The laboratory must then label each individual container. Usually the information necessary to classify the contents of the container appropriately is contained on the shipping label and should be noted. Important first-aid information is also usually provided on this label.

Even though OSHA prescribes the use of labels or other appropriate warnings at present, no single uniform labeling system for hazardous chemicals exists for clinical laboratories. Appropriate hazard warnings include any words, pictures, symbols, or combinations that convey the health or physical hazards of the container's contents and must be specific as to the effect of the chemical and the specific target organs involved.[21] The National Fire Protection Association (NFPA) has developed the 704-M Identification System, which classifies hazardous material from 0 to 4 (most hazardous) according to flammability and reactivity (instability). This system uses diamond-shaped labels, which are available from most companies that sell laboratory safety equipment. The labels are color coded and are divided into quadrants. Three of the quadrants have a characteristic color and represent a type of hazard. A number in the quadrant indicates the degree of the hazard. The fourth (lower) quadrant contains information of special interest to firemen; for example, "W" indicates a water-ignitable material (Figure 1-6, *B*). Some chemicals require labels using two or three of the quadrants to convey the necessary information.

Descriptive labels, such as "corrosive," "flammable," "poison," and "explosives" may also be used. Obviously, some containers may require two or three labels because several types of hazard are involved.

Kits of assorted safety signs are available from most laboratory supply dealers. These contain most general labels necessary in a clinical laboratory. Some examples of the contents of one kit are "eye wash," "use in hood," "safety shower," "empty cylinder," and "wear eye protection in this area."

Biological Hazards

To operate a clinical laboratory safely, it is essential to minimize the exposure of laboratory workers to infectious agents, such as the hepatitis viruses and the human immunodeficiency virus (HIV). Exposure to infectious agents results from (1) accidental puncture with needles, (2) spraying of infectious materials by a syringe or spilling and splattering of these materials on bench tops or floors, (3) centrifuge accidents, and (4) cuts or scratches from contaminated vessels. Any unfixed tissue, including blood slides, must also be treated as potentially infectious material.

As discussed earlier in this section, OSHA has mandated that all U.S. laboratories have an exposure control plan.[42] In addition, the National Institute for Occupational Safety and Health (NIOSH), a functional unit of the CDC, has prepared and widely distributed a document entitled Universal Precautions that specifies how U.S. clinical laboratories handle infectious agents.[35] In general it mandates that clinical laboratories treat all human blood and other potentially infectious materials as if they were known to contain infectious agents, such as HBV, HIV, and other blood-borne pathogens. These requirements apply to all specimens of blood, serum, plasma, blood products, vaginal secretions, semen, cerebrospinal fluid, synovial fluid, and concentrated HBV or HIV viruses. In addition, any specimen of any type that contains visible traces of blood should be handled using these Universal Precautions.

Universal Precautions also specify that barrier protection must be used by laboratory workers to prevent skin and mucous membrane contamination from specimens. These barriers, also known as PPE, include gloves, gowns, laboratory coats, face shields or mask and eye protection, mouth pieces, resuscitation bags, pocket masks, or other ventilator devices. Soon it was noted that latex allergy can be a problem when using latex gloves for barrier protection. By September 1992, 1100 reactions and 15 fatalities related to latex allergy had been reported to the Food and Drug Administration (FDA).[22] If latex gloves are to be used, they should be powder-free, low-allergen latex. A variety of medical grade nonlatex gloves made of materials such as vinyl, nitrile, neoprene or thermoplastic elastomer is available. The cost varies considerably.

New products for increasing employee protection against needle sticks include an array of novel sharps containers and biological safety disposal bags and needle sheaths that may be closed following venipuncture without physically touching the needle or the sheath. Although additional studies are required on their efficacy and effects on laboratory test results, microlaser devices are now available for piercing a patient's skin to collect a capillary blood specimen.

The NCCLS has also published a similar set of recommendations,[27,32] several of which are specified as requirements in the OSHA exposure control plan. They include:

1. Never perform mouth pipetting and never blow out pipettes that contain potentially infectious material.
2. Do not mix potentially infectious material by bubbling air through the liquid.
3. Barrier protection, such as gloves, masks, and protective eye wear and gowns, must be available and used when drawing blood from a patient and when handling all patient specimens. This includes the removal of stoppers from tubes. Gloves must be disposable, nonsterile latex, or of other material to provide adequate barrier protection. Phlebotomists must change gloves and adequately dispose of them between drawing blood from different patients.
4. Wash hands whenever gloves are changed.
5. Facial barrier protection should be used if there is a significant potential for the spattering of blood or body fluids.
6. Avoid using syringes whenever possible and dispose of needles in rigid containers (Figure 1-7, *A*) without handling them (Figure 1-7, *B*).
7. Dispose of all sharps appropriately.
8. Wear protective clothing, which serves as an effective barrier against potentially infective materials. When leaving the laboratory, the protective clothing should be removed.
9. Strive to prevent accidental injuries.

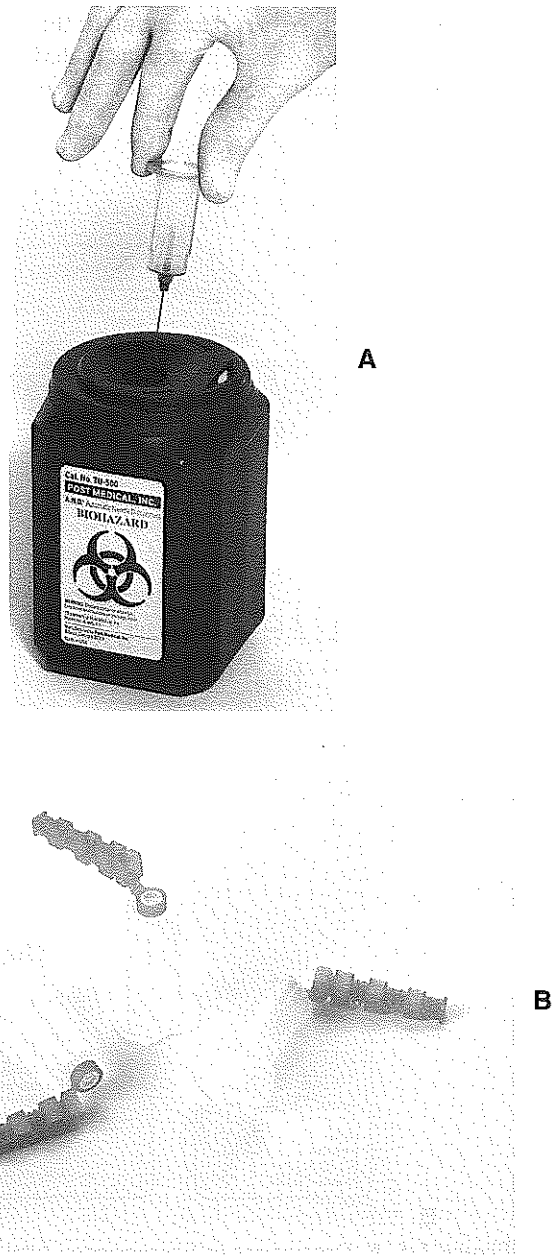

Figure 1-7 A, Convenient needle disposal system for sharps. **B,** Needle sheathing devices for prevention of body contact with needle. *(B Courtesy MarketLab Inc.)*

10. Encourage frequent hand washing in the laboratory; employees must wash their hands whenever they leave the laboratory.
11. Make a habit of keeping your hands away from your mouth, nose, eyes, and any other mucous membranes. This reduces the possibility of self-inoculation.
12. Minimize spills and spatters.
13. Decontaminate all surfaces and reusable devices after use with appropriate U.S. Environmental Protection Agency (EPA)–registered hospital disinfectants. Sterilization, disinfection, and decontamination are discussed in detail in NCCLS publication M29-T2.[27]
14. No warning labels are to be used on patient specimens since all should be treated as potentially hazardous.
15. Biosafety level 2 procedures should be used whenever appropriate.
16. Before centrifuging tubes, inspect them for cracks. Inspect the inside of the trunnion cup for signs of erosion or adhering matter. Be sure that rubber cushions are free from all bits of glass.
17. Use biohazard disposal techniques (e.g., "Red Bag").
18. Never leave a discarded tube or infected material unattended or unlabeled.
19. Periodically, clean out freezer and dry-ice chests to remove broken ampoules and tubes of biological specimens. Use rubber gloves and respiratory protection during this cleaning.
20. OSHA requires that hepatitis B vaccine be offered to all employees at risk of potential exposure as a regular or occasional part of their duties. CDC's Advisory Committee on Immunization Practices (ACIP) recommends that medical technologists, phlebotomists, and pathologists be vaccinated with hepatitis B vaccine. It is a regulatory mandate that all of the above laboratory employees at a minimum at least be given the option to freely receive the hepatitis B vaccine.

Investigation of tragic air accidents in the late 1990s by the U.S. National Transportation Safety Board (NTSB) led to the DOT, in cooperation with the International Air Transport Association (IATA) and the International Civil Aviation Organization (ICAO), developing revised and strict requirements for the shipping and handling of hazardous materials.[3,20] With the continued awareness of the necessity for Universal Precautions, the risk of blood-borne pathogens and the potentially adverse consequences of serious infection, the shipping and handling of Class 6 toxic materials—biological materials—is a critical safety issue.

The federal shipping and packaging guidelines[51] divide potentially infectious specimens or substances into the following risk groups:

1. A microorganism unlikely to cause human or animal disease. Materials containing only such microorganisms are not subject to the requirements of these regulations. The risk to individuals and the community is very low.
2. A pathogen that can cause human or animal disease, but is unlikely to be a serious hazard and, although capable of causing serious infection on exposure, for which there are effective treatments and preventive measure available and the risk of spread of infection is limited. Risk to individuals is moderate, but the risk to the community is low.
3. A pathogen that usually causes serious human or animal disease but does not ordinarily spread from one infected individual to another, and for which effective treatments and preventive measures are available. Risk to individuals is high, but risk to the community is low.
4. A pathogen that usually causes serious human or animal disease and that can be readily transmitted from one individual to another, directly or indirectly, and for which effective treatments and preventive measures are not usually available. Risk to the individual and the community is high.

These regulations place particular emphasis on the Hazardous Material (HAZMAT) training that must be given to laboratory employees when shipping and handling infectious substances. Elements include general awareness and familiarization, function-specific, and safety training. Proper training, particularly in the areas of package labeling and documentation (including a shipper's declaration of contents for dangerous goods), is mandatory with documented certification required from employers that the relevant employees have appropriate training programs. Although the adverse impact of improper training can be reflected most by potential human morbidity and mortality, identified violations of these regulations also carry large financial fines and penalties for both the infringing individual and the employer or institution.

Chemical Hazards

The proper storage and use of chemicals is necessary to prevent dangers, such as burns, explosions, fires, and toxic fumes. Thus knowledge of the properties of the chemicals in use and of proper handling procedures greatly reduces dangerous situations. Bottles of chemicals and solutions should also be handled carefully, and a cart should be used to transport a heavy or a multiple number of containers from one area to another. Glass containers with chemicals should be transported in rubber or plastic containers that protect them from breakage and, in the event of breakage, contain the spill. Appropriate spill kits should be available in strategic locations. A general spill kit, such as the Sasco Solidifier Spill Response Kit, should contain specific materials to be used with spills of acid or of caustic or organic materials. Directions for use of these materials are contained in the kit.

Spattering from acids, caustic materials, and strong oxidizing agents probably represents the greatest hazard to clothing and eyes and is a potential source of chemical burns. A bottle should never be held by its neck but instead firmly around its body with one or both hands, depending on the size of the bottle. Acids must be diluted by slowly adding them to water while mixing; water should never be added to concentrated acid. When working with acid or alkali solutions, safety glasses should be worn. Acids, caustic materials,

and strong oxidizing agents should be mixed in the sink. This provides water for cooling and for confinement of the reagent in the event the flask or bottle breaks.

All bottles containing reagents must be properly labeled. It is good practice to label the container before adding the reagent, thus preventing the possibility of having an unlabeled reagent. The label should bear the name and concentration of the reagent, the initials of the person who made up the reagent, and the date on which the reagent was prepared. When appropriate, the expiration date should also be included. The labels should be color coded or an additional label added to designate specific storage instructions, such as the requirement for refrigeration or special storage related to a potential hazard. All reagents found in unlabeled bottles should be disposed of using the appropriate procedures and precautions.

Strong acids, caustic materials, and strong oxidizing agents should be dispensed by a commercially available automatic dispensing device. Under no circumstances is mouth pipetting permitted.

In some instances, all waste materials are not collected in the same container. With certain pieces of equipment, strong acids or other hazardous materials are pumped directly into the drain. This should always be accompanied by a steady flow of water from the faucet. Safety glasses should be used by instrument operators when acids are pumped under pressure.

Perchloric acid, because it is potentially explosive in contact with organic materials, requires careful handling. Perchloric acid should not be used on wooden bench tops, and bottles of this acid should be stored on a glass tray. Disposal may be accomplished by adding the acid dropwise (using a splatter shield) to at least 100 volumes of cold water and pouring the diluted acid down the drain with large amounts of additional cold water. Special perchloric acid hoods, with special wash-down facilities, should be installed if large amounts of this acid are used.

Special care is necessary when dealing with mercury. Even small drops of mercury on bench tops and floors may poison the atmosphere in a poorly ventilated room. The element's ability to amalgamate with a number of metals is well known. After an accidental spillage of mercury, the spill area should be cleaned carefully until there are no droplets remaining. All containers of mercury should be kept well stoppered.

The EPA controls the disposal of nonradioactive hazardous wastes.[47] The Resource Conservation and Recovery Act of 1976 (RCRA) states that disposal of materials classifiable within any of the nine UN hazardous materials classes is enforced in such a way that health and safety professionals involved in the disposal of such materials are personally liable for each individual violation.

A NCCLS publication[28] covers hazardous waste disposal; however, many municipalities and states have their own regulations. The agencies should be contacted by the laboratory for specifics.

Volatile chemicals and compressed gases pose specific hazards.

Hazards from Volatiles

The use of organic solvents in a clinical laboratory represents a potential fire hazard and hazards to health from inhalation of toxic vapors or skin contact. These solvents should be used in a fume hood. Storage of organic solvents is regulated by rules set down by OSHA (Table 1-16). However, some local fire department rules are more stringent. Solvents should be stored in an OSHA-approved metal storage cabinet that is properly vented. The maximum working volume of flam-

TABLE 1-16 Maximum Allowable Size of Containers for Storage of Solvents Inside Buildings (OSHA)

	Maximum Allowable Size of Containers			
Container Type	**Class IA**	**Class IB**	**Class IC**	**Classes II and III**
Glass or approved plastic	1 pt	1 qt	1 gal	1 gal
Safety cans*	1 gal	2 gal	5 gal	5 gal
Metal drums (DOT)	60 gal	60 gal	60 gal	60 gal

Definitions of Classes	
IA	Flash point below 22.8 °C and boiling point below 37.8 °C
IB	Flash point below 22.8 °C and boiling point above 37.8 °C
IC	Flash point between 22.8 °C and 37.8 °C
II	Flash point between 37.8 °C and 60 °C
III	Flash point above 60 °C

OSHA, Occupational Safety and Health Administration; *DOT*, Department of Transportation.

*Safety cans are metal or plastic containers having a spring-closing spout cover designed to relieve internal pressure when subjected to the heat of fire and prevent leakage if tipped over. They are also equipped with a flame-arrester screen. Portable safety cans range in size from 1 pint to 5 gallons and are made in numerous styles with faucets, pouring spouts, or dispensing hoses. Only FM (Factory Mutual Engineering Corporation of the Factory Mutual System) or UL (Underwriters Laboratories, Inc.) recognized safety cans should be used, because these cans have been tested and approved by these agencies.

mable solvents allowed outside storage cabinets is 5 gallons per room. No more than 60 gallons of type I and II solvents may be stored in a single cabinet. No more than three cabinets may be located in each 5000 sq ft of laboratory space. Larger amounts than shown in Table 1-16 must be stored in special refrigerated storage rooms or in outside storage buildings.

Vaporization is the major problem in the ignition and spread of fires. Vapors from flammable and combustible liquids and solids form a flammable mixture with air. They are characterized by their flash point, where the flash point is defined as the lowest temperature at which a solvent gives off flammable vapors in the close vicinity of its surface. The mixture at its flash point ignites when exposed to a source of ignition. At temperatures below the flash point, the vapor given off is considered too lean for ignition.

Disposal of flammable solvents in storm sewers or sanitary sewers is, in general, not allowed. Exceptions are small amounts of those materials that are miscible with water, but even disposal of these should be followed by large amounts of cold water. Other solvents should be collected in safety cans. Separate cans should be used for ether and for chlorinated solvents; all other solvents may be combined in a third can. The cans should be stored, in keeping with storage quantity rules, in a safety cabinet until pickup by a waste-disposal firm. A more economical approach is to transfer the solvents to larger cans or drums in an outside storage facility so that pickup could be less frequent. Some large institutions have their own in-house disposal facilities.

Hazards from Compressed Gases

The DOT regulations cover the labeling of cylinders of compressed gases that are transported by interstate carriers. The diamond-shaped labels described previously are used on all large cylinders and on any boxes containing small cylinders. Some general rules for handling large cylinders of compressed gas are:

1. Always transport cylinders using a hand truck to which the cylinder is secured.
2. Leave the valve cap on a cylinder until the cylinder is ready for use, at which time the cylinder should have been secured by a support around the upper one third of its body. Disconnect the hose or regulator, shut off the valve, and replace the cap before the cylinder is completely empty to prevent the possibility of the development of a negative pressure. Place an "empty" sign or label on the cylinder.
3. Chain or secure cylinders at all times even when empty.
4. Always check cylinders for the composition of their contents before connection.
5. Never force threads; if a regulator does not thread readily, something is wrong.

The precautions cited for large refillable gas cylinders also apply to small cylinders that are not refillable. Propane cylinders of the type frequently secured to a flame photometer and cylinders of calibrating gases for blood gas equipment are examples of disposable cylinders. Cylinders in floor-standing base supports require the additional security of a chain or strap attached to a wall or fixed piece of furniture. Local fire department regulations (which vary considerably from place to place) govern the disposal of exhausted cylinders.

Electrical Hazards

Wherever there are electrical wires or connections, there is a potential for shock or fire hazard. Worn wires on all electrical equipment should be replaced immediately; all equipment should be grounded using three-prong plugs. OSHA regulations stipulate that the requirements for grounding of electrical equipment of the National Electrical Code (published by NFPA) be met. If grounded receptacles are not available, a licensed electrician should be consulted for proper alternative grounding techniques. Some local codes are more stringent than OSHA requirements and do not allow for two-pole mating receptacles with adapters for a three-pole plug.

Use of extension cords is prohibited. This standard is more stringent than any other existing regulation. In some instances, an extension cord may have to be used temporarily. In such cases, the cord should be less than 12 feet in length, have at least 16 American Wire Gauge (AWG) wire, be approved by the Underwriters Laboratory (UL), and have only one outlet at the end. If several outlets are necessary in an area, a power strip with its own fuse or circuit breaker may be installed at least 3 inches above bench top level. Several manufacturers now sell devices to check for high resistance in neutral or ground wiring or excess voltage in the neutral wiring.

Electrical equipment and connections should not be handled with wet hands, nor should electrical equipment be used after liquid has been spilled on it. The equipment must be turned off immediately and dried thoroughly; a fan or hair dryer will speed up the drying process. In case of a wet or malfunctioning electrical instrument that is used by several people, the plug should be pulled and a note cautioning co-workers against use should be left on the instrument.

Fire Hazards

The ideal solution to the problem of fires and indeed to all laboratory accidents is prevention. However, all fires cannot be prevented, so provisions must be made for those that do occur. NFPA and OSHA publish standards covering subjects from emergency exits (including means of egress) to safety and firefighting equipment. NFPA also publishes the National Fire Codes. Many state and local agencies have adopted these codes (some of which are more stringent than OSHA requirements) and thus make them legally enforceable.

Every laboratory should have the necessary equipment to put out or to confine a fire in the laboratory and to put out a fire on the clothing of an individual. Easy access to safety showers is essential. A safety shower should have a pull chain

TABLE 1-17 Classification of Fires and Fire Extinguisher Requirements

Type of Hazard	Class of Fire	Recommended Extinguisher Agents
Ordinary combustibles: Wood, cloth, paper	A	Water, dry chemical foam, loaded steam
Flammable liquids and gases: Solvents and greases Natural or manufactured gases	B	Dry chemical, carbon dioxide, loaded steam, Halon 1211 or 1301 foam
Electrical equipment: Any energized electrical equipment. If electricity is turned off at source, this reverts to a Class A or B	C	Dry chemical, carbon dioxide, Halon 1211 or 1301
Combinations of: Ordinary combustibles and flammable liquids and gases	A & B	Dry chemical, loaded steam, foam
Combinations of: Ordinary combustibles and electrical equipment	A & C	Dry chemical
Combinations of: Flammable liquids and gases and electrical equipment	B & C	Dry chemical, carbon dioxide, Halon 1211 or 1301
Combinations of: Ordinary combustibles, flammable liquids and gases, and electrical equipment	A, B, & C	Triplex dry chemical

either attached to the wall at a convenient height or hanging down from the shower head; the chain should have a large ring attached so that the shower may be easily activated, even with eyes closed. Fire blankets for smothering fire on clothing should be available in an easily accessible wall-mounted case. The blanket is unrolled from the case and rolled around the body by taking hold of the rope that is attached to the blanket and turning the body around. The location of this equipment and the locations of fire alarms and maps of evacuation routes are dictated by the local fire marshal.

Various types of fire extinguishers are available. The type to use depends on the type of fire. Because it is impractical to have several types of fire extinguishers present in every area, dry chemical fire extinguishers are among the best all-purpose extinguishers for laboratory areas. An extinguisher should be provided near every laboratory door and, in a large laboratory, at the end of the room opposite to the door. Everyone in the laboratory should be instructed in the use of these extinguishers and any other firefighting equipment. All fire extinguishers should be tested by qualified personnel at intervals specified by the manufacturer. The three classes of fires and the type of fire extinguisher to be used for each are listed in Table 1-17. Every fire extinguisher is labeled as to the type of fire it should be used to extinguish.

Two additional types of fires, designated "D" and "E," should be handled only by trained personnel. Type "D" fires include those involving powdered metal materials (e.g., magnesium). A special powder is used to fight this hazard. A type "E" fire is one that cannot be put out or is liable to result in a detonation (such as an arsenal fire). A type "E" fire is usually allowed to burn out while nearby materials are being appropriately protected.

Many clinical laboratories now have a computer that is housed in a temperature- and humidity-controlled room. The most popular automatic fire control system used for these rooms is Halon 1301 (bromotrifluoromethane). Although this is the least toxic of the halons, NFPA regulations require a warning sign at the entrance to the room and availability of self-contained breathing equipment.

CHAPTER 2

Specimen Collection and Processing

Donald S. Young, M.B., Ph.D.,
Edward W. Bermes, Jr., Ph.D.,
and Doris M. Haverstick, Ph.D.

In this chapter, we discuss proper specimen collection techniques, processing, and storage of common sample types and the aspects of these activities that affect test values and their interpretation.

SPECIMEN COLLECTION

Many errors can occur during the collection, processing, and transport of biological specimens. Minimizing these errors will result in more reliable information for use by healthcare professionals. Examples of biological specimens that are analyzed in clinical laboratories include whole blood; serum; plasma; urine; feces; saliva; spinal, synovial, amniotic, pleural, pericardial, and ascitic fluids; and various types of solid tissue. The National Committee for Clinical Laboratory Standards (NCCLS) has published several procedures for collecting many of these specimens under standardized conditions.[9-12,14] In addition, the NCCLS has published documents related to sample collection and analysis for specialized tests, such as sweat chloride (see also Chapter 27).

BLOOD

Blood for analysis may be obtained from veins, arteries, or capillaries. Venous blood is usually the specimen of choice, and *venipuncture* is the method for obtaining this specimen.[12] In young children and for many point-of-care tests, *skin puncture* is frequently used to obtain what is mostly capillary blood; *arterial puncture* is used mainly for blood gas analyses.

Venipuncture

In the clinical laboratory, venipuncture is defined as all of the steps involved in obtaining an appropriate identified blood specimen from a patient's vein.[12]

Preliminary Steps

Before any specimen is collected, the phlebotomist must confirm the identity of the patient. (See Chapter 11 for discussion of techniques used for identification.) This entails the patient stating his or her name and the phlebotomist verifying information on the patient's wrist band, if the patient is hospitalized. If the patient is an outpatient, the phlebotomist must ask the patient to state his or her name and confirming information on the test requisition form with identifying information provided by the patient. At least three items of identification should be used (e.g., name, medical record number, date of birth, room location if the patient is hospitalized or address if the patient is an outpatient). In specialized situations, such as tests for alcohol or other tests of medicolegal importance, establishment of a chain of custody for the specimen may require additional patient identification, such as a photo. Before collection of a specimen, a phlebotomist should be properly dressed in personal protective equipment, such as an impervious gown and gloves. If the phlebotomist is to collect a specimen from a patient in isolation in a hospital, the phlebotomist should notify one of the patient's nurses that he or she is about to collect a blood specimen and must put on a clean gown and gloves and a face mask and goggles before entering the patient's room. The face mask limits the spread of potentially infectious droplets, and the goggles limit the possible entry

of infectious material into the eye. The extent of the precautions required will vary with the nature of a patient's illness and the institution's policies and bloodborne pathogen plan (see Chapter 1), to which a phlebotomist must adhere. If airborne precautions are indicated, the phlebotomist must wear a N95 TB respirator.

If appropriate the phlebotomist should verify that the patient is fasting. The patient should be comfortably seated or supine, if sitting is not feasible, and should have been in this position for 20 minutes before the specimen is drawn. This standardization minimizes differences in concentrations of blood constituents caused by variations in blood volume (hemoconcentration or hemodilution). Either of the patient's arms should be extended in a straight line from the shoulder to the wrist. An arm with an inserted intravenous line should be avoided, as should an arm with extensive scarring or a hematoma at the intended collection site. If a woman has had a mastectomy, arm veins on that side of the body should not be used because the surgery may have caused lymphostasis, affecting the blood composition. If a woman has had double mastectomies, blood should be drawn from the arm of the side on which the first procedure was done. If the surgery was done within 6 months on both sides, a vein on the back of the hand or at the ankle should be used.

Before performing a venipuncture, the phlebotomist should estimate the volume of blood to be drawn and select the appropriate number and types of tubes for the blood, plasma, or serum tests requested. An appropriate needle must also be selected. The most commonly used sizes are gauges 19 to 22. The larger the gauge size is, the smaller the bore. The usual choice for an adult with normal veins is gauge 20; if veins tend to collapse easily, a size 21 is preferred. For volumes of blood from 30 to 50 mL, an 18-gauge needle may be required to ensure adequate blood flow. A needle is typically 1.5 inches (3.7 cm) long, but 1-inch (2.5-cm) needles are also used. All needles must be sterile, sharp, and without barbs. If blood is drawn for trace element measurements, the needle should be stainless steel and known to be free from contamination. For trace element determinations, all apparatus coming in contact with the specimen should be acid washed or known to be free of trace metal contamination (see Chapter 30).

Location

The median cubital vein in the antecubital fossa, or crook of the elbow, is the preferred site for collecting venous blood in adults because the vein is both large and close to the surface of the skin. Veins on the back of the hand or at the ankle may be used, although these are less desirable and should be avoided in diabetics and other individuals with poor circulation. It is appropriate to collect blood through a cannula that is being inserted for long-term fluid infusions at the time of first insertion to avoid a second stick. In severely ill individuals or those requiring many intravenous injections, an alternative blood-drawing site should be chosen. Selection of a vein for puncture is facilitated by palpation. An arm containing a cannula or arteriovenous fistula should not be used without consent of the patient's physician. If fluid is being infused intravenously into a limb, the fluid should be shut off for 3 minutes before a specimen is obtained and a suitable note made in the patient's chart and on the result report form. Specimens obtained from the opposite arm or below the infusion site in the same arm may be satisfactory for most tests except for those analytes that are contained in the infused solutions (e.g., glucose or electrolytes).[16]

Preparation of Site

The area around the intended puncture site should be cleaned with a prepackaged alcohol swab or with a gauze pad saturated with 70% isopropanol. Cleaning of the puncture site should be done with a circular motion and from the site outward. The skin should be allowed to dry in the air. No alcohol should remain on the skin, because traces may cause hemolysis and invalidate test results. When specimens are to be collected for ethanol determinations, the skin should be cleaned with a benzalkonium chloride solution (Zephiran Chloride solution, 1:750) that is free of alcohol. Povidone-iodine should be avoided as a cleaning agent because it may interfere with several chemistry procedures. Once the skin has been cleaned, it should not be touched until after the venipuncture has been completed.

Timing

The time at which a specimen is obtained is important for those blood constituents that undergo marked diurnal variation (e.g., corticosteroids and iron) and for those used to monitor drug therapy (see Chapter 33). Furthermore, timing is important in relation to specimens for alcohol or drug measurements in association with medicolegal considerations.

Venous Occlusion

After the skin is cleaned, either a blood pressure cuff or a tourniquet is applied 4 to 6 inches (10 to 15 cm) above the intended puncture site. This obstructs the return of venous blood to the heart and distends the veins. When a blood pressure cuff is used as a tourniquet, it is usually inflated to approximately 60 mm Hg (8.0 kPa). Tourniquets are typically made from precut soft rubber strips or from Velcro type of bands. It is rarely necessary to leave a tourniquet in place for longer than 1 minute, but even within this short time the composition of blood changes. Although the changes that occur in 1 minute are slight, marked changes have been observed after 3 minutes (Table 2-1).

The composition of blood drawn first—that is, the blood closest to the tourniquet—is most representative of the composition of circulating blood. The first-drawn specimen should therefore be used for those analytes such as calcium that are pertinent to critical medical decisions. Blood drawn later shows a greater effect from venous stasis. Thus the first tube may show a 5% increase of protein, whereas the third

TABLE 2-1 Changes in Composition of Serum When Venous Occlusion Is Prolonged from 1 Minute to 3 Minutes*

Increase	%	Decrease	%
Total protein	4.9	Potassium	6.2
Iron	6.7		
Total lipids	4.7		
Cholesterol	5.1		
Aspartate aminotransferase	9.3		
Bilirubin	8.4		

From Statland BE, Bokelund H, Winkel P: Factors contributing to intraindividual variation of serum constituents: 4. Effects of posture and tourniquet application on variation of serum constituents in healthy subjects. Clin Chem. 1974;20:1513-19.
Mean values obtained from 11 healthy individuals
*To estimate the probable effect of a factor on results, relate percent increase or decrease shown (or intimated) in table to analytical variation (± % CV) routinely found for analytes.

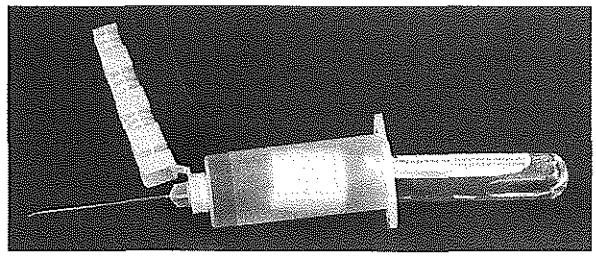

Figure 2-1 Assembled venipuncture set. *(From Flynn, JC: Procedures in Phlebotomy. 3rd ed. Saunders, St Louis, 2005, p 84.)*

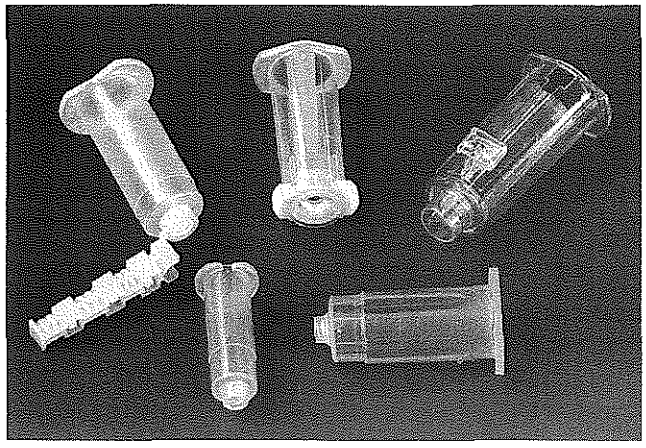

Figure 2-2 Various tube holders used in venipuncture. *(From Flynn, JC: Procedures in Phlebotomy. 2nd ed. W. B. Saunders, Philadelphia, 1999, p79.)*

tube may show a 10% change.[8] The concentration of protein-bound constituents is also influenced by stasis. Prolonged stasis may increase the concentration of protein or protein-bound constituents by as much as 15%. A uniform procedure for order of draw for tests should therefore be established (see below). If it is possible to collect only a small volume of blood, the priority of which tests to perform should be established.

The increase in activity of creatine kinase and aspartate aminotransferase in serum seen after venipuncture may be caused by hemoconcentration, by the slight trauma to tissue as the needle pierces the skin, and by stasis of blood in the tissue.

Pumping of the fist before venipuncture should be avoided because it causes an increase in the plasma potassium, phosphate, and lactate concentrations. The lowering of the blood pH by accumulation of lactate causes the plasma ionized calcium concentration to increase. The ionized calcium concentration reverts to normal 10 minutes after the tourniquet is released.

Stress associated with blood collection can have effects in patients at any age. As a consequence, plasma concentrations of cortisol and growth hormone may increase. Stress occurs particularly in young children who are frightened, struggling, and held in physical restraint. Collection under these conditions may cause adrenal stimulation leading to an increased plasma glucose concentration or create increases in the serum activities of enzymes that originate in skeletal muscle.

Collection with Evacuated Blood Tube

Evacuated blood tubes are usually considered to be less expensive and more convenient and easier to use than syringes. There are several types of evacuated tubes used for venipuncture collection. They vary by the type of additive added and volume of the tube. The different types are identified by the color of the stopper used (Table 2-2). Some glass tubes are siliconized to reduce adhesion of clots to walls or stoppers and to decrease risk of hemolysis. Blood collected into a tube containing one additive should never be transferred into other tubes, because the first additive may interfere with tests for which a different additive is specified. Thrombin is added to some tubes to accelerate clotting. However, the silicone-coated wall may also activate and accelerate the clotting mechanism.

A typical system for collecting blood in evacuated tubes is shown in Figure 2-1. This is an example of a recently introduced single-use device that incorporates a cover that can be safely placed over the needle when sample collection is complete. A needle is screwed into the collection tube holder (Figure 2-2), and the tube is then gently inserted into this holder. Before use, the tube should be gently tapped to dislodge any additive from the stopper before the needle is inserted into a vein; this prevents aspiration of the additive into the patient's vein. Both single-draw and multidraw needles are available.

After the skin is cleaned, the needle should be guided gently into the patient's vein (Figure 2-3); once the needle is in place, the tube should be pressed forward into the holder

TABLE 2-2 Coding of Stopper Color to Indicate Additive in Evacuated Blood Tube

Tube Type	Additive	Stopper Color	Alternative
Gel separation tubes	Polymer gel/silica activator	Red/black	Gold
	Polymer gel/silica activator/lithium heparin	Green/gray	Light gray
Serum tubes (nonadditive)	Silicone-coated interior	Red	Red
	Uncoated interior	Red	Pink
Serum tubes (with additives)	Thrombin (dry additive)	Gray/yellow	Orange
	Particulate clot activator	Yellow/red	Red
	Thrombin (dry additive)	Light blue	Light blue
Whole blood/plasma tubes	K_2EDTA (dry additive)	Lavender	Lavender
	K_3EDTA (liquid additive)		
	Na_2EDTA (dry additive)		
	Citrate, trisodium (coagulation)	Light blue	Light blue
	Citrate, trisodium (erythrocyte sedimentation rate)	Black	Black
	Sodium fluoride (antiglycolic agent)	Gray	Light (lt) gray
	Heparin, lithium (dry or liquid additive)	Green	Green
	Potassium oxalate	Light gray	Light gray
	Lithium iodoacetate	Light gray	Light gray
Special chemistry tubes			
Lead	Heparin, sodium (liquid additive)	Brown	Brown
	Heparin, sodium (dry additive)	Royal blue	Royal blue
Trace elements	Silicone-coated interior (serum tube)	Royal blue	Royal blue
Stat chemistry	Thrombin	Gray/yellow	Orange
Plasma preparation tube*	K_2EDTA (dry additive)/polymer gel/silica activator	Opalescent white	Opalescent white

Modified from the National Committee for Clinical Laboratory Standards: Evacuated Tubes and Additives for Blood Specimen Collection: Approved Standard H1-A4. 4th ed. Wayne PA:National Committee for Clinical Laboratory Standards, 1996 and information listed in the Becton Dickinson Web page (http://www.bd.com/).

*The Plasma Preparation Tube™ (Becton Dickinson, Franklin Lakes, New Jersey) is a plastic evacuated tube used for the collection of venous blood that upon centrifugation separates undiluted plasma for use in molecular diagnostic test methods.

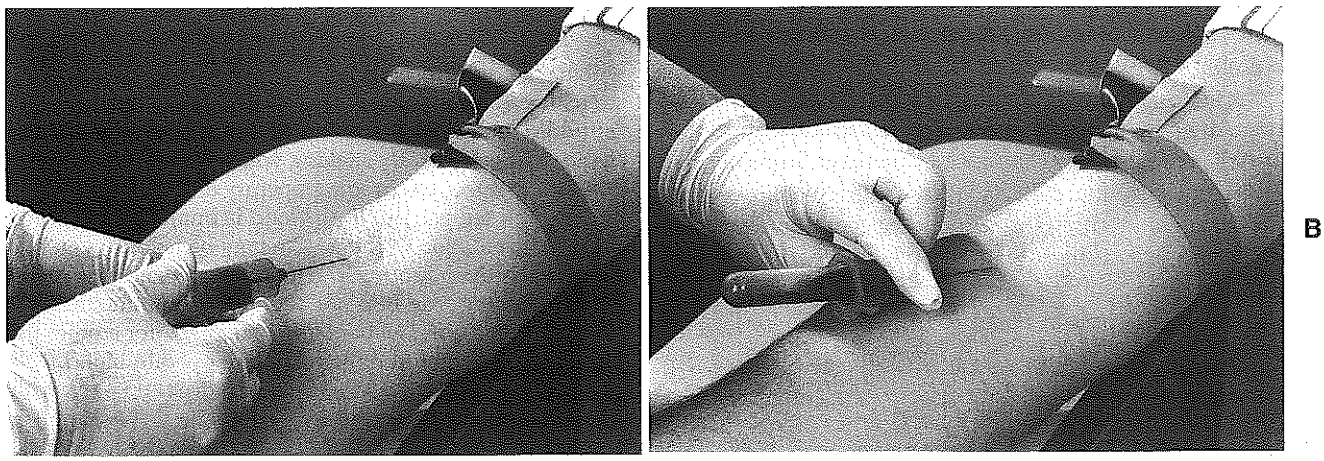

Figure 2-3 Venipuncture. *(From Flynn, JC: Procedures in Phlebotomy. 2nd ed. W. B. Saunders, Philadelphia, 1999, p94.)*

to puncture the stopper and release the vacuum. When blood begins to flow into the tube, the tourniquet should be released without moving the needle. The tube is filled until the vacuum is exhausted, and the tube can then be withdrawn from the holder and replaced by another tube, if this is necessary. Other tubes may be filled if required using the same technique with the holder in place. When several tubes are required from a single blood collection, a shut-off valve—consisting of rubber tubing that slides over the needle opening inside the tube—is used to prevent spillage of blood during exchange of tubes.

Serum separator tubes are available (Table 2-2) that contain an inert, thixotropic, polymer gel material with a specific gravity of approximately 1.04.[5] Aspiration of blood into the tube and subsequent centrifugation displace the gel, which settles like a disk between cells and supernatant when the tube is centrifuged. Relative centrifugal force (RCF) must be at least 1100 ×g for gel release and barrier formation. Release of intracellular components into the supernatant is prevented by the barrier for several hours or, in some cases, for a few days. These separator tubes may be used as primary containers from which serum can be directly aspirated by a number of analytical instruments.

Evacuated blood tubes may be made of soda-lime or borosilicate glass or plastic (polyethylene terephthalate). Because of the decreased likelihood of breakage and hence exposure to infectious materials, many laboratories have converted from glass tubes to plastic tubes. Tubes made from the soda-lime glass may release trace elements, particularly calcium and magnesium, into solutions. Special tubes are available for trace element determination (Table 2-2).

Stoppers may contain zinc, invalidating the use of evacuated blood tubes for zinc measurement, and TBEP (tris[2-butoxyethyl] phosphate), a constituent of rubber, which may interfere with the measurement of certain drugs. With time, the vacuum in evacuated tubes is lost and their effective draw diminishes. The silicone coating also decays with age. Therefore the stock of these tubes should be rotated and careful attention paid to the expiration date. Problems with evacuated blood tubes also arise when too little blood is collected into the tubes (short draw). Although an incorrect draw is of little consequence when clotted blood is required, a disproportionate ratio of blood to anticoagulant may affect some hematology and other special tests. Therefore some tubes from each batch should be checked for volume of draw before the lot is put in use.

In a few patients, backflow from blood tubes into veins occurs owing to a decrease in venous pressure. The dangerous consequences of this occurrence may be prevented if only sterile tubes are used for collection of blood. Backflow is minimized if the arm is held downward and blood is kept from contact with the stopper during the collection procedure. To minimize problems if backflow should occur and to optimize the quality of specimens—especially to prevent cross contamination with anticoagulants—blood should be collected into tubes in the following order: (1) blood cultures, (2) nonadditive tubes (red stopper), (3) coagulation- or citrate-containing tube (blue stopper), (4) serum separator tube containing gel (red stopper with black flecks), (5) heparin-containing tube (green stopper), (6) EDTA-containing tube (lavender stopper) and oxalate-fluoride–containing tube (gray stopper).

Blood Collection with Syringe

Syringes are customarily used for patients with difficult veins. If a syringe is used, the needle is placed firmly over the nozzle of the syringe and the cover of the needle is removed. If the syringe has an eccentric nozzle, the needle should be arranged with the nozzle downward but the bevel of the needle upward. The syringe and needle should be aligned with the vein to be entered and the needle pushed into the vein at an angle to the skin of approximately 15° (Figure 2-3). When the initial resistance of the vein wall is overcome as it is pierced, forward pressure on the syringe is eased, and the blood is withdrawn by gently pulling back the plunger of the syringe. Should a second syringe be necessary, a gauze pad may be placed under the hub of the needle to absorb the spill; the first syringe is then quickly disconnected and the second put in place to continue the draw. After removal of the needle from the syringe, drawn blood should be quickly transferred by gentle ejection into tubes prepared for its receipt. The tubes should then be capped if they contain an additive or anticoagulant, and then gently mixed (5 to 10 inversions).

Vigorous suction on a syringe during collection or forceful transfer from the syringe to the receiving vessel may cause hemolysis of blood. Hemolysis is usually less when blood is drawn through a small-bore needle because turbulence of the blood is less than when a larger-bore needle is used.

Completion of Collection

When blood collection is complete and the needle withdrawn, the patient is instructed to hold a dry gauze pad over the puncture site, with the arm raised to lessen the likelihood of leakage of blood. The pad can subsequently be held in place by a bandage, which can be removed after 15 minutes. The phlebotomist must separate the needle from the syringe or collection tube and discard it into a sharps container. On completion of the collection, the phlebotomist must dispose of his or her gloves in a hazardous waste receptacle before proceeding to the next patient.

Venipuncture in Children

The techniques for venipuncture in children and adults are similar. However, children are likely to make unexpected movements, and assistance in holding them still is often desirable. Either a syringe or evacuated blood tube system may be used to collect specimens. A syringe should be either the tuberculin type or a 3-mL-capacity syringe, except when a large volume of blood is required for analysis. A 21- to 23-gauge needle or 20- to 23-gauge butterfly needle with attached tubing is appropriate to collect specimens.

Skin Puncture

Skin puncture is an open collection technique in which the skin is punctured by a lancet[10] and a small volume of blood collected into a microdevice, such as a capillary tube. In practice it is used in situations where (1) sample volume is limited (e.g., pediatric applications), (2) repeated venipunctures have resulted in severe vein damage, or (3) patients may have been burned or bandaged and veins are therefore unavailable for venipuncture. This technique is also commonly used when the sample is to be applied directly to a testing device in a point-of-care testing situation, such as whole blood glucose or hemoglobin testing. It is most often performed on the tip of a finger, on an earlobe, and on the heel or big toe of infants. For example, in an infant younger than 1 year of age, the lateral or medial plantar surface of the foot should be used for skin puncture; suitable areas are illustrated in Figure 2-4. In older children, the plantar surface of the big toe may also be used, although blood collection should be avoided on ambulatory patients from anywhere on the foot. The proper procedure for collecting blood from infants is described in the NCCLS standard H4-A4.[10]

To collect a blood specimen by a skin puncture, the phlebotomist first thoroughly cleans the skin with a gauze pad saturated with 70% isopropanol. All alcohol must be allowed to evaporate from the skin so that hemolysis does not occur. When the skin is dry, it is quickly punctured by a sharp stab with a lancet. The depth of the incision should be less than 2.5 mm to avoid contact with bone.[1] To minimize the possibility of infection, a different site should be selected for each finger puncture. The finger should be held in such a way that gravity assists the collection of blood on the finger tip. Massage of the finger to stimulate blood flow should be avoided, because it causes the outflow of debris and of tissue fluid, which does not have the same composition as plasma. To improve circulation of the blood, the finger may be warmed by application of a warm, wet washcloth for 3 minutes before pricking. The first drop of blood is wiped off, and subsequent drops are transferred to the appropriate collection tube by gentle contact. Filling should be done rapidly to prevent clotting, and introduction of air bubbles should be avoided.

Blood may be collected into capillary blood tubes by capillary action. A variety of collection tubes is commercially available (Figure 2-5). Such containers can be purchased with different anticoagulants, such as sodium and ammonium heparin, and some can be obtained in brown glass for collection of light-sensitive analytes, such as bilirubin. There are also many small plastic or glass tubes that can be used to collect blood. A disadvantage of some of the collection devices shown in Figure 2-5 is that blood tends to pool in the mouth of the tube and must be flicked down the tube with a risk of hemolysis. Drop-by-drop collection should be avoided because it increases hemolysis.

For the collection of blood specimens on filter paper for neonatal screening and, increasingly, molecular genetics testing, the skin is cleaned and punctured as described previously. Then the filter paper is gently touched against a large drop of blood, which is allowed to soak into the paper to fill the marked circle. Only a single application per circle should be made. The paper is examined to verify that there has been complete penetration of the paper. The procedure is repeated to fill all the circles. Avoid milking or squeezing of the foot, because this procedure contributes tissue fluids. The filter papers should be air dried. Blood should not be transferred onto filter paper after it has been collected in capillary tubes because partial clotting may have occurred.

Arterial Puncture

Arterial puncture requires considerable skill and is usually performed only by physicians or specially trained technicians or nurses. The preferred sites of arterial puncture are, in order, the (1) radial artery at the wrist, (2) brachial artery in the elbow, and (3) femoral artery in the groin. Because leakage of blood from the femoral artery tends to be greater, especially in the elderly, sites in the arm are most often used. The proper technique for arterial puncture is described in NCCLS Standard H11-A3.[11]

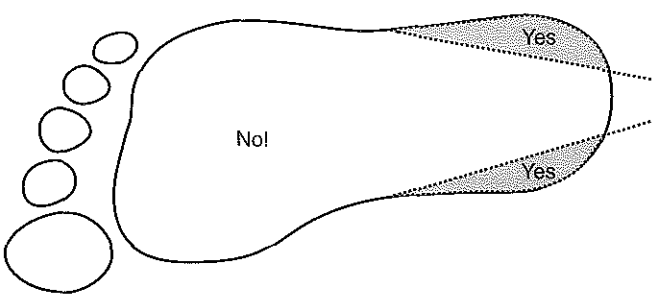

Figure 2-4 Acceptable sites for skin puncture to collect blood from an infant's foot. *(Modified from Blumenfeld TA, Turi GK, Blanc WA. Recommended site and depth of newborn heel punctures based on anatomical measurements and histopathology. Reprinted with permission from Elsevier [The Lancet 1979, 1, 230-233].)*

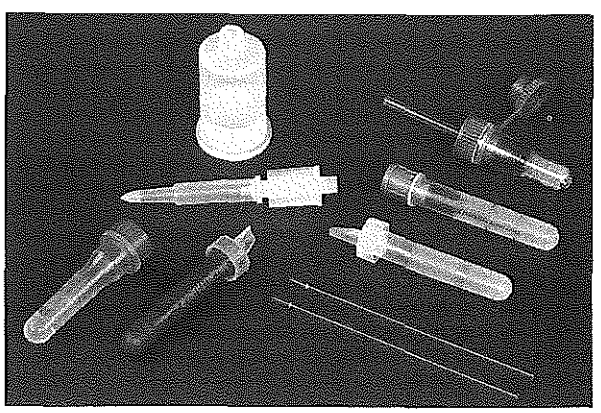

Figure 2-5 Microcollection tubes. *(From Flynn, JC: Procedures in Phlebotomy. 3rd ed. Saunders, St Louis, 2005, p 78.)*

In the neonate, an indwelling catheter in the umbilical artery is best to obtain specimens for blood gas analysis. In the older child or adult in whom it is impossible to perform an arterial puncture, a capillary puncture may be performed to obtain *arterialized capillary blood.* Such a specimen yields acceptable values for pH and PCO_2, but not always for PO_2. In the older child or adult, the preferred puncture site is the earlobe; in the young child or infant, it is the heel. Capillary blood specimens are particularly inappropriate when the blood circulation is poor and thus should be avoided when a patient has reduced cardiac output, hypotension, or vasoconstriction. For each capillary puncture, the skin should first be warmed with a hot, moist towel to improve the circulation. The puncture itself should be performed as described previously; a free flow of blood is essential. Heparinized capillary tubes containing a small metal bar are used to collect the blood. Tubes should be sealed quickly and the contents mixed well by using a magnet to move the metal bar up and down in the tube so that a uniform specimen is available for analysis.

Anticoagulants and Preservatives for Blood

Serum is the specimen of choice for many assay systems. Sometimes considerable differences may be observed between the concentrations of analytes in serum and plasma as shown in Table 2-3.[4] However, some assay systems require a whole blood or plasma specimen. If so an anticoagulant must be added to the specimen during the collection procedure. A number of anticoagulants are used including heparin, EDTA, sodium fluoride, citrate, oxalate, and iodoacetate.

Heparin

Heparin is the most widely used anticoagulant and causes the least interference with tests,[7] except for tests performed using polymerase chain reaction (PCR). It is a mucoitin polysulfuric acid and is available as sodium, potassium, lithium, and ammonium salts. This anticoagulant accelerates the action of antithrombin III, which neutralizes thrombin and thus prevents the formation of fibrin from fibrinogen. Most blood tubes are prepared with approximately 0.2 mg heparin for each milliliter of blood (1000 units/mL) to be collected. The heparin is usually present as a dry powder that is hygroscopic and dissolves rapidly.

Heparin has the disadvantage of high cost and temporary action, and it produces a blue background in blood smears that are stained with Wright's stain. In addition, heparin is said to inhibit acid phosphatase activity and to interfere with the binding of calcium to EDTA in analytical methods for calcium involving complexing with EDTA. It has also been reported to affect the binding of triiodothyronine and thyroxine to their carrier proteins, thus producing higher free concentrations of these hormones.

EDTA

EDTA is a chelating agent that is particularly useful for hematological examinations because it preserves the cellular components of blood. It is used as the disodium, dipotassium, or tripotassium salt, the last two being more soluble. It is effective at a final concentration of 1 to 2 g/L of blood. Higher concentrations hypertonically shrink the red cells. EDTA prevents coagulation by binding calcium, which is essential for the clotting mechanism. Blood collection tubes are prepared by adding a 0.1% solution of an EDTA salt followed by evaporation of water at room temperature.

EDTA, probably by chelation of metallic cofactors, inhibits alkaline phosphatase, creatine kinase, and leucine aminopeptidase activities. Because it chelates calcium and iron, EDTA is unsuitable for specimens for calcium and iron analyses using photometric or titrimetric techniques. As an

TABLE 2-3 Differences in Composition Between Plasma and Serum*

Plasma Value Greater Than Serum	Value (%)	No Difference Between Serum and Plasma Values	Plasma Value Less Than Serum	Value (%)

anticoagulant, it has little effect on other clinical tests although the concentration of cholesterol has been reported to be decreased by 3% to 5%.

Sodium Fluoride

Sodium fluoride is a weak anticoagulant but is often added as a preservative for blood glucose. As a preservative, together with another anticoagulant such as potassium oxalate, it is effective at a concentration of approximately 2 g/L blood. It exerts its preservative action by inhibiting the enzyme systems involved in glycolysis. Most specimens are preserved at 25°C for 24 hours or at 4°C for 48 hours. Without an antiglycolytic agent, the blood glucose concentration decreases approximately 100 mg/L (0.56 mmol/L) per hour at 25°C. The rate of decrease is faster in newborns because of the increased metabolic activity of their erythrocytes and in leukemic patients because of the high metabolic activity of the white cells. Sodium fluoride is poorly soluble, and blood must be well mixed before effective antiglycolysis occurs.

When sodium fluoride is used alone for anticoagulation, three to five times greater concentrations than the usual 2 g/L are required. This high concentration and the inhibition of the glycolytic cycle are likely to cause fluid shifts and a change in the concentration of some analytes. Fluoride is also a potent inhibitor of many serum enzymes and in high concentrations also affects urease, used to measure urea nitrogen in many analytical systems.

Citrate

Sodium citrate solution, at a concentration of 34 to 38 g/L in a ratio of 1 part to 9 parts of blood, is widely used for coagulation studies because the effect is easily reversible by addition of Ca^{2+}. Because citrate chelates calcium, it is unsuitable as an anticoagulant for specimens for measurement of this element. It also inhibits aminotransferases and alkaline phosphatase but stimulates acid phosphatase when phenylphosphate is used as a substrate. Because citrate complexes molybdate, it decreases the color yield in phosphate measurements that involve molybdate ions and produces low results.

Oxalates

Sodium, potassium, ammonium, and lithium oxalates inhibit blood coagulation by forming rather insoluble complexes with calcium ions. Potassium oxalate ($K_2C_2O_4 \cdot H_2O$), at a concentration of approximately 1 to 2 g/L of blood, is the most widely used oxalate. At concentrations of greater than 3 g oxalate per liter hemolysis is likely to occur.

Combined ammonium and/or potassium oxalate does not cause shrinkage of erythrocytes. However, other oxalates can cause shrinkage by drawing water into the plasma. Reduction in hematocrit may be as much as 10%, causing a reduction in the concentration of plasma constituents of 5%. As fluid is lost from the cells, an exchange of electrolytes and other constituents across the cell membrane occurs. Oxalate inhibits several enzymes, including acid and alkaline phosphatases, amylase, and lactate dehydrogenase, and may cause precipitation of calcium as the oxalate salt.

Iodoacetate

Sodium iodoacetate at a concentration of 2 g/L is an effective antiglycolytic agent and a substitute for sodium fluoride. Because it has no effect on urease, it can be used when glucose and urea tests are performed on a single specimen. It inhibits creatine kinase but appears to have no notable effects on other clinical tests.

Influence of Site of Collection on Blood Composition

Blood obtained from different sites differs in composition. Skin puncture blood is more like arterial blood than venous blood. Thus there are no clinically significant differences between freely flowing capillary blood and arterial blood in pH, PCO_2, PO_2, and oxygen saturation. The PCO_2 of venous blood is up to 6 to 7 mm Hg (0.8-0.9 kPa) higher. Venous blood glucose is as much as 70 mg/L (0.39 mmol/L) less than the capillary blood glucose.

Blood obtained by skin puncture is contaminated to some extent with interstitial and intracellular fluids. The major differences between venous serum and capillary serum are illustrated in Table 2-4.

TABLE 2-5 Influence of Collection Site on Composition of Plasma*

	Arterial	Central Venous	Peripheral Venous
Alanine aminotransferase (U/L)	62	61	81

Collection of Blood from Intravenous or Arterial Lines

When blood is collected from a central venous catheter or arterial line, it is necessary to ensure that the composition of the specimen is not affected by the fluid that is infused into the patient. The fluid is shut off using the stopcock on the catheter, and 10 mL of blood is aspirated through the stopcock and discarded before the specimen for analysis is withdrawn. Blood properly collected from a central venous catheter and compared with blood drawn from a peripheral vein at the same time shows notable differences in composition. A comparison of arterial blood with central and peripheral venous blood is illustrated in Table 2-5.

Blood may be collected from the veins of an arm below an intravenous line without interference from the fluid being infused, because retrograde blood flow does not occur in the veins, and the fluid that is infused must first circulate through the heart and return to the tissue before it reaches the sampling site.

Hemolysis

Hemolysis is defined as the disruption of the red cell membrane and results in the release of hemoglobin. Serum shows visual evidence of hemolysis when the hemoglobin concentration exceeds 200 mg/L. Slight hemolysis has little effect on most test values. Severe hemolysis causes a slight dilutional effect on those constituents present at a lower concentration in the erythrocytes than in plasma. However, a notable effect may be observed on those constituents that are present at a higher concentration in erythrocytes other than in plasma. Thus plasma activities or concentrations of aldolase, total acid phosphatase, lactate dehydrogenase, isocitrate dehydrogenase, potassium, magnesium, and phosphate are particularly increased by hemolysis. The inorganic phosphate in serum increases rapidly as the organic esters in the cells are hydrolyzed. Aspartate aminotransferase activity is increased by 2% for each 100 mg of hemoglobin per liter. One hundred milligrams hemoglobin per liter increases serum lactate dehydrogenase activity by 10% and serum potassium concentration by 0.6%. An additional band caused by hemoglobin may be observed on serum protein electrophoresis.

Although the amount of free hemoglobin could be measured and a calculation made to correct test values affected by hemoglobin,[2] this practice is undesirable because factors other than hemoglobin could contribute to the altered test values, and it would be impossible to assess their impact. Hemolysis may affect many unblanked or inadequately blanked analytical methods.[19]

URINE

The type of urine specimen to be collected is dictated by the tests to be performed. Untimed or random specimens are suitable for only a few chemical tests; usually, urine specimens must be collected over a predetermined interval of time, such as 1, 4, or 24 hours. A *clean, early morning, fasting specimen* is usually the most concentrated specimen and thus is preferred for microscopic examinations and for the detection of abnormal amounts of constituents, such as proteins, or of unusual compounds, such as chorionic gonadotropin. The *clean timed specimen* is one obtained at specific times of the day or during certain phases of the act of micturition. Bacterial examination of the first 10 mL of urine voided is most appropriate to detect urethritis, whereas the midstream

specimen is best for investigating bladder disorders. The *double-voided specimen* is the urine excreted during a timed period after a complete emptying of the bladder; it is used, for example, to assess glucose excretion during a glucose tolerance test. Its collection must be timed in relation to the ingestion of glucose. Similarly, in some metabolic disorders, urine must be collected during or immediately after symptoms of the disease appear (see Chapter 32 on porphyrins).

When they are to be tested for their alcohol and drugs of abuse content, urine specimens are collected under rigorous conditions requiring chain of custody documentation. (See Chapter 34 for details of such a collection.)

Catheter specimens are used for microbiological examination in critically ill patients or in those with urinary tract obstruction but should not normally be obtained just for examination of chemical constituents. The *suprapubic tap specimen* is a useful alternative, because the tap is unlikely to cause infection. After appropriate cleaning of the skin over the full bladder, a 22-gauge spinal needle is passed through a small wheal made by a local anesthetic. The bladder is penetrated and the urine withdrawn into the syringe.

Even though tests in the clinical laboratory are not usually affected by lack of sterile collection procedures, the patient's genitalia should be cleaned before each voiding to minimize the transfer of surface bacteria to the urine. Cleansing is essential if the true concentration of white cells is to be obtained. Details of collection of urine specimens are contained in an NCCLS guideline.[14]

Timed Urine Specimens

The collection period for timed specimens should be long enough to minimize the influence of short-term biological variations. When specimens are to be collected over a specified period of time, the patient's close adherence to instructions is important. The bladder must be emptied at the time the collection is to begin, and this urine is discarded. Thereafter all urine must be collected until the end of the scheduled time. If a patient has a bowel movement during the collection period, precautions should be taken to prevent fecal contamination. If a collection has to be made over several hours, urine should be passed into a separate container at each voiding and then emptied into a larger container for the complete specimen. This two-step procedure prevents the danger of a patient's splashing himself or herself with a preservative, such as acid. The large container should be stored at 4 °C in a refrigerator during the entire collection period.

Before beginning a timed collection, a patient should be given written instructions with regard to diet or drug ingestion if appropriate to avoid interference of ingested compounds with analytical procedures. Thus instructions for collection of specimens for 5-hydroxyindoleacetic acid measurements should specify avoidance of avocados, bananas, plums, walnuts, pineapples, eggplant, acetaminophen, and cough syrups containing glyceryl guaiacolate (guaifenesin). The dietary components are sources of 5-hydroxytryptamine and should be avoided for this reason; the other compounds interfere with certain analytical procedures but may not interfere with highly specific analytical methods. The staff of each laboratory should determine its own requirements. See also specimen information for specific analytes in the respective chapters.

For 2-hour specimens, a prelabeled 1-L bottle is generally adequate. For a 12-hour collection, a 2-L bottle usually suffices; for a 24-hour collection, a 3- or 4-L bottle is appropriate for most patients. A single bottle allows adequate mixing of the specimen and prevents possible loss of some of the specimen if a second container does not reach the laboratory. Urine should not be collected at the same time for two or more tests requiring different preservatives. Aliquots for an analysis such as a microscopic examination should not be removed while a 24-hour collection is in process. Removal of aliquots is not permissible even when the volume removed is measured and corrected because the excretion of most compounds varies throughout the day, and test results will be affected. Appropriate information regarding the collection, including warnings with respect to handling of the specimen, should appear on the bottle label.

Collection of Urine from Children

Collection of a timed specimen from an infant is difficult, but fortunately such specimens are rarely required. The scrotal or perineal area is first cleaned and dried, and any natural or applied skin oils are removed. For an untimed specimen, a plastic bag (U-bag, Hollister Inc, Chicago IL; or Tink-Col, C.R. Bard, Inc, Murray Hill, NJ) is placed around the infant's genitalia and left in place until urine has been voided.

A metabolic bed is used to collect timed specimens from infants. The infant lies on a fine screen above a funnel-shaped base containing a drain under which a container is placed to receive urine. The fine screen retains fecal material. Nevertheless, the urine is likely to be contaminated, to some extent, by such material.

To obtain a sterile urine specimen for culture from an infant, a suprapubic tap is performed. The collection of specimens from older children is done as in adults, using assistance from a parent when this is necessary.

Urine Preservatives

The most common preservatives and the tests for which the preservatives are required are listed in Table 2-6. Preservatives have different roles but are usually added to reduce bacterial action or chemical decomposition or to solubilize constituents that might otherwise precipitate out of solution. Another application is to decrease atmospheric oxidation of unstable compounds. Some specimens should not have *any* preservatives added because of the possibility of interference with analytical methods.

One of the most acceptable forms of preservation of urine specimens is *refrigeration* immediately after collection; it is even more successful when combined with chemical preservation. Urinary preservative tablets that contain a mixture of

chemicals, such as potassium acid phosphate, sodium benzoate, benzoic acid, hexamethylene tetramine, sodium bicarbonate, and mercuric oxide (Starplex Scientific, Inc, www.starplexscientific.com), have been used for chemical and microscopic examination. Because these tablets contain sodium and potassium salts among others, they should not be used for analysis of these analytes. The preservative tablets act mainly by lowering the pH of the urine and by releasing formaldehyde. *Formalin* has also been used for preserving specimens, but in large amounts it precipitates urea and inhibits certain reactions (e.g., the dipstick esterase test for leukocytes). Acidification to below pH 3 is widely used to preserve 24-hour specimens and is particularly useful for specimens for calcium, steroids, and vanillylmandelic acid (VMA) determinations (10 mL HCl, 6 mol/L, per 24-hour excretion). However, precipitation of urates will occur, thereby rendering a specimen unsuitable for measurement of uric acid.

Sulfamic acid (10 g/L urine) has also been used to reduce pH. *Boric acid* (5 mg/30 mL) has been used, but it too causes precipitation of urates. Although *thymol* and *chloroform* were widely used in the past to preserve specimens for chemical and microscopic urinalysis, it is now recognized that specimens for these tests should be analyzed immediately, and that the addition of preservatives is both largely ineffective and a source of interference with several analytical methods. *Toluene* is the only organic solvent that is still used as a preservative. When present in a large enough amount, it acts as a barrier between the air and the surface of the specimen. Toluene, however, does not prevent the growth of anaerobic microorganisms and, because of its flammable nature, is a safety hazard. A mild base, such as *sodium bicarbonate* or a small amount of sodium hydroxide (NaOH), is used to preserve porphyrins, urobilinogen, and uric acid. A sufficient quantity should be added to adjust the pH to between 8 and 9.

When a timed collection is complete, the specimen should be delivered without delay to the clinical laboratory, where the volume should be measured. This may be done by using graduated cylinders or by weighing the container and urine when preweighed or uniform containers are used. The mass in grams may be reported as if it were the volume in milliliters. There is rarely a need to measure the specific gravity of a weighed specimen because errors in analysis usually exceed the error arising from failure to correct the volume of urine for its mass. Nevertheless, it is relatively easy to apply a simple mathematical correction based on an average specific gravity or to measure the specific gravity and to derive a correct volume for each specimen.

Before a specimen is transferred into small containers for each of the ordered tests, it must be thoroughly mixed to ensure homogeneity because the specific gravity, volume, and composition of the urine may all vary throughout the collection period. The small container into which an aliquot is transferred should not be a plastic bottle if toluene or another organic compound has been used as a preservative; metal-free containers must be used for trace metal analyses.

Feces

Small aliquots of feces are frequently analyzed to detect the presence of "hidden" blood, so-called *occult blood,* which is recognized as one of the most effective clues to the presence of a bleeding ulcer or malignant disease in the gastrointestinal tract. The utility of screening for occult blood is that it is included as part of many periodic health examinations. Tests for occult blood should be done on aliquots of excreted stools rather than on material obtained on the glove of a physician doing a rectal examination, because this procedure may cause enough bleeding to produce a positive result. In other instances, the small amount of stool present on the glove may not be representative of the whole, so that bleeding may not be recognized. Patients have even been encouraged to recover, by means of a spatula, small parts of feces that have been excreted into a toilet bowl and apply them directly to the reagent-impregnated slides used for the detection of blood. These specimens are then mailed or delivered to a laboratory for analysis (see also Chapter 48).

Feces from children may be screened for tryptic activity to detect cystic fibrosis. In the infant, fecal material for these tests is usually recovered from the child's diaper. See Chapter 21 for a discussion of the measurement of trypsin in feces.

In adults, measurement of fecal nitrogen and fat in 72-hour specimens is used to assess the severity of malabsorption; measurement of fecal porphyrins is occasionally required to characterize the type of porphyria (see Chapter 32).Usually, no preservative is added to the feces, but the container should be kept refrigerated throughout the collection period and care should be taken to prevent contamination from urine. When the collection is complete, the container and feces are weighed, and the mass of excreted feces is calculated. The specimen is homogenized and aliquotted so that the amount of fat or nitrogen excreted per day and the proportion of dietary intake excreted can be calculated.

For metabolic balance studies, collections of stool are usually made over a 72-hour period. Many balance studies are carried out in conjunction with research on the metabolism of such elements as calcium. It is important for such studies that a patient be on a controlled diet for a sufficiently long time before the commencement of the study, so that a steady state has been attained.

Spinal Fluid

Spinal fluid is normally obtained from the lumbar region, although a physician may occasionally request analysis of fluid obtained during surgery from the cervical region or from a cistern or ventricle of the brain. Spinal fluid is examined when there is a question as to the presence of a cerebrovascular accident, meningitis, demyelinating disease, or meningeal involvement in malignant disease. Lumbar punctures should always be performed by a physician. The physician thoroughly cleans the skin of the lumbar region below the termination of the spinal cord where the cauda equina goes through the spinal canal. He or she makes a small bleb in the skin over the space between the third and fourth or fourth and fifth lumbar vertebrae with 2% procaine and then introduces a spinal needle (22-gauge, 3.5 inches [9 cm] long) through the bleb into the spinal canal. He or she measures the pressure with a manometer and then allows 3 to 4 mL of fluid to drip into plain tubes. The tubes should be sterile, especially if microbiological tests are required. Because the initial specimen may be contaminated by tissue debris or skin bacteria, the first tube should be used for chemical or serological tests, the second for microbiological tests, and the third for microscopic and cytological examination. The same procedure is used for infants and children, but the volume of fluid withdrawn should be the minimum for the requested tests.

Up to 20 mL of spinal fluid can be safely removed from an adult, although this amount is not usually required. Antiglycolytic agents usually are not added to the tube for glucose measurement; rapid processing of specimens, a clinical requirement for tests on spinal fluid, ensures that little metabolism of glucose occurs even in the presence of many bacteria. To allow proper interpretation of spinal fluid glucose values, a simultaneous blood specimen should be obtained.

Synovial Fluid

The technique of obtaining synovial fluid for examination is called *arthrocentesis.* Synovial fluid is withdrawn from joints to aid characterization of the type of arthritis and to differentiate noninflammatory effusions from inflammatory fluids. Normally, only a very small amount of fluid is present in any joint, but this volume is usually very much increased in the presence of inflammatory conditions. Arthrocentesis should be performed by a physician using sterile procedures, and the technique must be modified from joint to joint

depending on the anatomical location and size of the joint. The skin over the joint is cleaned with an antiseptic, such as iodine, and then anesthetized with an agent like ethyl chloride. A needle of appropriate size is introduced into the joint and the required amount of fluid aspirated into the syringe. The physician should establish priorities for the tests to be performed in case the available volume is insufficient for all tests. Sterile plain tubes should be used for culture and for glucose and protein measurements; an EDTA tube is necessary for a total leukocyte, differential, and erythrocyte count. Microscopic slides are prepared for staining with Gram's or other stains indicated and for visual inspection.

Amniotic Fluid (Amniocentesis)

Amniocentesis is performed by a physician for prenatal diagnosis of congenital disorders, to assess fetal maturity, or to look for Rh isoimmunization or intrauterine infection. Although ultrasound is not essential, amniocentesis is best performed with its assistance to aid localization of the placenta and to determine the presentation of the fetus. The best sites for obtaining amniotic fluid are behind the neck of the fetus, below its head, or from other unoccupied areas of the amniotic cavity.

The skin is cleaned and anesthetized as for other similar procedures, and 10 mL of fluid is aspirated into a syringe connected to the spinal needle that is typically used. Sterile containers such as polypropylene test tubes or urine cups are used to transport the fluid to the laboratory. If a specimen is for the determination of the lecithin-sphingomyelin (L/S) ratio, the container is immediately placed in ice; if it is for spectrophotometric analysis, the specimen should be transferred to a brown tube or bottle to prevent photodegradation of bilirubin. Alternatively the specimen container may be wrapped in aluminum foil.

There are few complications from amniocentesis. Occasionally a bloody tap is made. The blood may come from the uterine wall, the placenta, or even the fetus. Determination of fetal hemoglobin can be used to help ascertain the source if it is important to do so.

Pleural, Pericardial, and Ascitic Fluids

The pleural, pericardial, and peritoneal cavities normally contain a small amount of serous fluid that lubricates the opposing parietal and visceral membrane surfaces. Inflammation or infections affecting the cavities cause fluid to accumulate. The fluid may be removed to determine if it is an effusion or an exudate, a distinction made possible by protein or enzyme analysis. The collection procedure is called *paracentesis*. When specifically applied to the pleural cavity, the procedure is a *thoracentesis;* if applied to the pericardial cavity, a *pericardiocentesis*. Paracenteses should be performed only by skilled and experienced physicians. Pericardiocentesis has now been largely supplanted by echocardiography.

The skin over the intended puncture site should be cleaned with 70% isopropanol and then allowed to dry in the air. A spinal needle is then inserted into the body cavity through a small bleb in the skin raised by injection of a local anesthetic. Fluid is then withdrawn by a syringe and transferred to appropriate tubes for analysis. Paracentesis is rarely associated with complications. Occasionally, blood-stained fluid is obtained because of puncture of a small blood vessel. If adhesions are present between the intestine and abdominal wall, a part of the intestine could be perforated by a peritoneal tap. With a thoracentesis, pneumothorax and bronchopleural fistulas are potential complications.

Saliva

Although measurements of concentrations of certain analytes in saliva have been advocated, the clinical application of methods using saliva has been limited. Exceptions are the measurement of blood group substances to determine secretor status and the genotype. Measurement of a drug in saliva (see Chapter 34) has been suggested to estimate the free, pharmacologically active concentration of the drug in serum. There is, however, a considerable difference in pH between saliva and serum, and ratios of bound-free drug would not be the same. Fortunately, ultrafiltration techniques are now available that facilitate the processing of serum for free drug analysis.

Several slightly different techniques have been devised for the collection of saliva. Usually an individual is asked to rinse out his or her mouth with water and then chew an inert material, such as a piece of rubber or paraffin wax, from 30 seconds to several minutes. The first mouthful of saliva is discarded; thereafter the saliva is collected into a small glass bottle.

Swabs

Although most commonly used for collection of specimens for microbiological testing, swabs are sometimes used to collect epithelial cells of the cheek for molecular genetics testing. A sterile Dacron or rayon swab with a plastic shaft is preferred because calcium alginate swabs or swabs with wooden sticks may contain substances that inhibit PCR-based testing. After collection, the swab may be stored in an air-tight plastic container or immersed in liquid, such as phosphate-buffered saline (PBS) or viral transport medium.

Solid Tissue

The solid tissue most often analyzed in the clinical laboratory is malignant tissue from the breast for estrogen and progesterone receptors. During surgery, at least 0.5 to 1 g tissue should be removed and trimmed of fat and nontumor material. The tissue should be quickly frozen, preferably in liquid nitrogen or in a mixture of dry ice and alcohol. The time between collection and freezing should be less than 20 minutes. A histological section should always be examined at the time of analysis of the specimen to confirm that the specimen is indeed malignant tissue. The same procedure may be used to obtain and prepare solid tissue for toxicological analysis; however, when trace element determinations

are to be made, all materials used in the collection or handling of the tissue should be made of plastic or materials known to be free of contaminating trace elements (see also Chapter 30).

Hair and Finger Nails

Hair and finger or toe nails have been used for trace metal analyses. However, collection procedures have been poorly standardized, and quantitative measurements are better obtained on blood or urine. Hair specimens have also been analyzed for their drug content (see Chapter 34).

HANDLING OF SPECIMENS FOR TESTING

Maintenance of Specimen Identification

Valid test results require a representative, properly collected, and properly preserved specimen. Proper identification of the specimen must be maintained (see Chapter 11 for discussion on the use of bar codes to identify specimens). Every specimen container must be adequately labeled even if the specimen must be placed in ice or if the container is so small that a label cannot be placed along the tube, as might happen with a capillary blood tube. Direct labeling of a capillary blood tube by folding the label like a flag around the tube is preferred; a less satisfactory alternative is to label a larger container into which the capillary tube can be placed. For small volumes of urine submitted in a screw-cap urine cup and any specimen submitted in a screw-cap test tube or cup, the label should be placed on the cup or tube directly, not to the cap. The minimum information on a label should include a patient's name, location, identifying number, and the date and time of collection. All labels should conform to the laboratory's stated requirements to facilitate proper processing of specimens. No specific labeling should be attached on specimens from patients with infectious diseases to suggest that these specimens should be handled with special care. All specimens should be treated as if they are potentially infectious. However, labels suggesting special handling for other purposes are sometimes indicated.

Preservation of Specimens in Transit

Although delays of a specimen in transit from a patient in a hospital to the laboratory are usually short, the time elapsing from the separation of serum and cells until analysis may be considerable. The specimen must be properly treated both during its transport to the laboratory and from the time the serum has been separated until it is analyzed. For some tests, specimens must be kept at 4 °C from the time the blood is drawn until the specimens are analyzed, or until the serum or plasma is separated from the cells. Examples are specimens for ammonia and blood gas determinations, such as PCO_2, PO_2, and blood pH (see Chapter 27). Transfer of these specimens to the laboratory must be done by placing the specimen container in ice water. Specimens for acid phosphatase, lactate and pyruvate, and certain hormone tests (e.g., gastrin and renin activity) should be treated the same way. A notable decrease in pyruvate and increase in lactate concentration occurs within a few minutes at ambient temperature (see Chapter 25).

For all test constituents that are thermally labile, serum and plasma should be separated from cells in a refrigerated centrifuge. Specimens for bilirubin or carotene and some drugs, such as methotrexate, must be protected from both daylight and fluorescent light to prevent photodegradation. Some special handling requirements are listed in Table 2-7.

Although transport of specimens from the patient to the clinical laboratory is often done by messenger, pneumatic tube systems have been used to move the specimens more rapidly over long distances within the hospital. Hemolysis may occur in these systems unless the tubes are completely filled and movement of the blood tubes inside the specimen carrier is prevented.[17] The pneumatic tube system should be designed to eliminate sharp curves and sudden stops of the specimen carriers, because these factors are responsible for much of the hemolysis that may occur. With many systems, however, the plasma hemoglobin concentration may be increased, and the serum activity of red cell enzymes, such as lactate dehydrogenase, may also be increased. Nonethe-

TABLE 2-7 Selected Blood Constituents Requiring Special Collection and Storage Conditions*†

Constituent	Anticoagulant	Handling Requirements
S-Acetone, acetoacetate†‡		Freeze; stopper
S-Acid phosphatase		Add citrate (10 g/L); freeze
P-ACTH (corticotropin)	Heparin, 0.2 g/L	Freeze within 15 min of collection
S-Alcohol		Add NaF (10 g/L) to serum
S-Aldolase		Freeze
P,S-Aldosterone		Add boric acid (25 g/L) or freeze
P-Amino acids	Heparin, 0.2 g/L	Freeze
S-Androstenedione		Draw sample in AM (0000-1200 hr)
S-Ascorbic acid		Freeze
S-Barbiturates		Do not use heparin
S-Bile acids		Freeze

TABLE 2-7 *Continued*

Constituent	Anticoagulant	Handling Requirements
S-C-peptide		Draw from fasting patient, freeze
S-Calcitonin		Freeze
P-Carcinoembryonic antigen (CEA)	EDTA, 2 g/L	
B-Cholinesterase	Heparin, 0.2 g/L	
S-Citric acid		Freeze
S-Complement		Freeze
P-Cortisol	Heparin, 0.2 g/L	Separate immediately
S-Creatine		Freeze
S-Creatine kinase isoenzymes		Freeze
S-Creatinine		Freeze
S-Cryoglobulins		Keep above 20 °C
P-11-Deoxycortisol	Heparin, 0.2 g/L	Separate immediately
P,S-Digitoxin		Draw 6-12 hr postadministration
S-Digoxin		Draw 8 hr postadministration
P-Estradiol	Heparin, 0.2 g/L	Freeze
P-Fatty acids (free and esterified)	Heparin, 0.2 g/L	Freeze
P-Fibrinogen	Citrate, ~4 g/L	Do not use heparin
S,B-Fluoride		Do not collect in glass container
P-Folate (tetrahydrofolate)		Freeze
B-Galactose	Heparin, 0.2 g/L	NaF (10 g/L) added with heparin
S-Gastrin		Collect from fasting patient; freeze
B-Glucose-6-phosphate dehydrogenase†	EDTA, 2 g/L	
P-HDL-cholesterol	EDTA, 2 g/L	Collected after 12-14 hr fast, freeze
B-Hemoglobins (for quantitation and electrophoresis)	EDTA, 2 g/L	
S-Histidine		Freeze
S-17-Hydroxyprogesterone		Draw between 0900 and 1100 hr
S-Insulin		Collect from fasting patient, freeze
S-Isocitrate dehydrogenase		Freeze
B-Lactate		Immediately dilute with an equal volume of 5% (50 g/L) perchloric acid, shake and mix
B-Lead	Heparin, 0.2 g/L	Collect in lead-free tube containing heparin
S-Lipoprotein phenotyping		Freeze
S-Lysozyme		Freeze
S-Magnesium		Separate immediately
S-Parathyroid hormone (PTH)		Freeze
S-Pepsinogen		Freeze
S-Placental lactogen		Freeze
S-Prolactin		Freeze
S-Prostaglandin $F_{2\alpha}$		Freeze
P-Pyridoxal phosphate (vitamin B_6)	EDTA, 2 g/L	Protect from light
B-Pyruvate		Immediately dilute with an equal volume of 5% (50 g/L) perchloric acid, shake and mix
P-Renin	EDTA, 2 g/L	Chill during collection, centrifugation
S-Vitamin A		Protect from light
S-Zinc		Use only acid-washed glass, prevent hemolysis

From Winsten S, Gordesky SE: Transportation of specimens. *In:* Selected methods of clinical chemistry. Vol. 9. Faulkner WR, Ed. Washington, DC, AACC Press, 1982:11-15.

P, Plasma; *S,* serum; *B,* whole blood; *EDTA,* ethylenediaminetetraacetate.

*All specimens listed, except those to be assayed for cryoglobulins, should be transported at temperatures below 15 °C, except as noted.

†A sealable styrofoam container with "freezer packs" is usually sufficient to keep specimen frozen for 12 hr. Solid CO_2 is necessary for longer periods.

‡There is some question as to whether this constituent remains stable even with this procedure.

less, the amount of hemolysis is usually so small that it can be ignored. In special cases, such as in a patient undergoing chemotherapy whose cells are fragile, samples should be centrifuged before being placed in the pneumatic tube system or identified as "messenger delivery only."

For specimens that are collected in a remote facility with infrequent transportation by courier to a central laboratory, proper specimen processing must be done in the remote facility so that appropriately separated and preserved plasma or serum is delivered to the laboratory. This necessitates that the remote facility has ready access to all commonly used preservatives and wet ice.

Separation and Storage of Specimens

Plasma or serum should be separated from cells as soon as possible and certainly within 2 hours.[6] Premature separation of serum, however, may permit continued formation of fibrin and lead to obstruction of sample probes in testing equipment. Coagulation in plain or silicone-coated glass tubes is usually complete in 20 to 30 minutes but is prolonged in plastic containers. If it is impossible to centrifuge a blood specimen within 2 hours, the specimen should be held at room temperature rather than at 4°C to decrease hemolysis. If the specimens cannot be analyzed at once, the separated serum should usually be stored in capped tubes at 4°C until analysis, both to maintain stability of the specimen and to reduce evaporation. If a specimen for a particular test is sufficiently unstable at 4°C, the serum specimen should be held at −20°C in a freezer capable of maintaining this temperature. Frost-free freezers should be avoided because they have a wide temperature swing during the freeze-thaw cycle. Note, however, that 4°C or −20°C is not the optimum storage temperature for all tests; some lactate dehydrogenase isoenzymes, for instance, are more stable at room temperature than at 4°C. Although changes in concentration of test constituents have been observed when serum is stored in a serum separator tube in a refrigerator for 24 hours, the changes do not appear to be large enough to be of clinical significance.

Specimen tubes should be centrifuged with stoppers in place. Closure reduces evaporation, which occurs rapidly in a warm centrifuge with the air currents set up by centrifugation. Stoppers also prevent aerosolization of infectious particles. Specimen tubes containing volatiles, such as ethanol, *must* be stoppered while they are spun. Centrifuging specimens with the stopper in place maintains anaerobic conditions, which are important in the measurement of carbon dioxide and ionized calcium. Removal of the stopper before centrifugation allows loss of carbon dioxide and an increase in blood pH. Control of pH is especially important for the enzymatic measurement of acid phosphatase, which is labile under alkaline conditions engendered by CO_2 loss. Indeed, once the serum is separated for acid phosphatase tests, a tablet of disodium citrate should be added to stabilize the pH at about 6.2.

Transport of Specimens

Before a referral laboratory is used for any tests, the quality of its work should be verified by the referring laboratory. Guidelines for selection and evaluation of a referral laboratory have been published.[15] The specimen handling requirements of the referral laboratory must be observed, and test results reported by a referral laboratory must be identified as such when they are filed in a patient's chart.

It should be assumed that transport from a referring laboratory to a referral laboratory may take as long as 72 hours. Under optimal conditions, a referring laboratory should retain enough specimen for retesting should an unanticipated problem arise during shipment. The tube used for holding a specimen *(primary container)* should be so constructed that the contents do not escape if the container is exposed to extremes of heat, cold, or sunlight.[18] Reduced pressure of 0.50 atmosphere (50 kPa) may be encountered during air transportation, together with vibration, and specimens should be protected by a suitable container from these adverse conditions. Variability of temperature is a significant factor in causing instability of test constituents.[3]

Polypropylene and polyethylene containers are usually suitable for specimen transport. Glass should be avoided because of its tendency to break. Polystyrene is also unsuitable because it may crack when frozen. The containers must be leak proof and should have a Teflon-lined screw cap that does not loosen under the variety of temperatures to which the container may be exposed. The materials of both stopper and container must be inert and must not have any effect on the concentration of the analyte.

The shipping or *secondary container* used to hold one or more specimen tubes or bottles must be constructed to prevent the tubes from knocking against each other. Corrugated, fiberboard, or styrofoam boxes designed to fit around a single specimen tube may be used. A padded shipping envelope provides adequate protection for shipping single specimens. When specimens are shipped as drops of blood on filter paper (e.g., for neonatal screening), the paper should be enclosed in a plastic bag that then can be mailed in a regular envelope.

For transportation of *frozen* or *refrigerated* specimens, a styrofoam container should be used. The container walls should be 1 inch (2.5 cm) thick to provide effective insulation. The container should be vented to prevent buildup of carbon dioxide under pressure and a possible explosion. Solid carbon dioxide (dry ice) is the most convenient refrigerant material for keeping specimens frozen, and temperatures as low as −70°C can be achieved. The amount of dry ice required in a container depends on the size of the container and the efficiency of its insulation and the time for which the specimens must be kept frozen. One piece of solid dry ice (about 3 inches × 4 inches × 1 inch) in a container with 1-inch styrofoam walls and a volume of 125 cubic inches (2000 cm^3) will maintain a single specimen frozen for 48 hours.

Various laws and regulations apply to the shipment of biological specimens. Although they theoretically apply only to etiological agents (known infectious agents), all specimens should be transported as if the same regulations applied.[13] Airlines have rigid regulations covering the transport of specimens. The airlines deem dry ice a hazardous material; therefore the transport of most clinical laboratory specimens is affected by the regulations.

The various modes of transport of specimens influence the shipping time and cost. Priority mail service is usually adequate within the United States if a delay of up to 3 days is acceptable. Express mail service ensures delivery within 24 hours, but it is available only between certain cities. Small-package service is available from many airlines, as is service by bus lines and train.

The cost of specimen transport is often included in the fee of a referral laboratory for each test. Many referral laboratories either provide their own courier service or contract with large national companies to provide such services.

The director of a referring laboratory has the responsibility to ensure that specimens will be adequately transported to the referral laboratory. He or she should determine the benefits of different services and should keep in mind that the fastest service is usually the most expensive. He or she should also know that specimens should not be sent to a referral laboratory at the end of the week, because more delays in transit occur during weekends than during the working week and deterioration of specimens is more likely.

Optical Techniques*

L.J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path.

Many determinations made in the clinical laboratory are based on measurements of radiant energy emitted, transmitted, absorbed, scattered, or reflected under controlled conditions. The principles involved in such measurements are considered in this chapter.

NATURE OF LIGHT

Electromagnetic radiation includes radiant energy that extends from cosmic rays with wavelengths as short as 10^{-9} nm up to radio waves longer than 1000 km. However, in this chapter the term *light* is used to describe radiant energy from the visible and ultraviolet portions of the spectrum (180 to 800 nm).

The wavelength of light, the distance between two peaks as the light travels in a wavelike manner, is expressed in nanometers (nm) for wavelengths commonly used in photometry. Other units include:

$$1\,\text{nm} = 1\,\text{millimicrons}\,(\text{m}\mu) = 10\,\text{Angstroms}\,(\text{Å}) = 10^{-9}\,\text{m}$$

In addition to possessing wavelength characteristics, light also has properties that indicate it is composed of discrete energy packets called *photons.* The relationship between the energy of photons and their frequency is given by the equation:

$$E = h\nu \qquad (1)$$

where E = energy in ergs, ν = frequency of light in cycles per second, and h = Planck's constant (6.62×10^{27} erg seconds). The frequency of light (ν) is related to the wavelength by an equation:

$$\nu = \frac{c}{\lambda} \qquad (2)$$

where c = speed of light in a vacuum (3×10^{10} cm/s), and λ = wavelength in centimeters. Combining equations (1) and (2) results in:

$$E = \frac{hc}{\lambda} \qquad (3)$$

This equation shows that the energy of light is inversely proportional to the wavelength. For example, ultraviolet (UV) radiation at 200 nm possesses greater energy than infrared (IR) radiation at 750 nm.

The human eye responds to radiant energy with wavelengths between about 380 and 750 nm, but modern instrumentation permits measurements at both shorter wavelength (UV) and longer wavelength (IR) portions of the spectrum. Sunlight, or light emitted from a tungsten filament, is a mixture or spectrum of radiant energy of different wavelengths that the eye recognizes as "white." Table 3-1 shows approximate relationships between wavelengths and color characteristics for the UV, visible, and short IR portions of the spectrum. Thus a solution will appear green when viewed against white light if it transmits light maximally between 500 and 580 nm but absorbs light at other wavelengths. Similarly a solid object appears green if it reflects light in this region (500 to 580 nm) but absorbs light at other portions of the spectrum. In general, if we compare the intensity of light transmitted by a colored solution to that of a blank or reference solution over the entire spectrum, we obtain a typical spectral transmittance curve characteristic for that spectrum. Such curves are shown in Figure 3-1 for solutions of nickel sulfate *(a)* and potassium permanganate *(b).* Inspection of the curves should lead us to predict that the color of solution *A* is green because light is transmitted maximally near the green portion of the spectrum. Curve *B,* on the other hand, illustrates the spectrum of a solution that transmits light maximally in the blue, violet, and red portions of the spectrum. The eye recognizes this mixture of colors as purple.

*The author gratefully acknowledges the original contributions by Dr. Merle A. Evenson and Dr. Thomas O. Tiffany, upon which portions of this chapter are based.

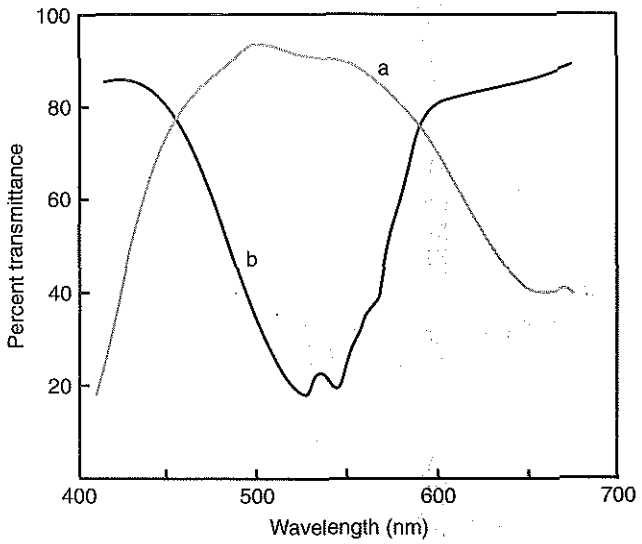

Figure 3-1 Spectral transmittance curves of nickel sulfate *(a)* and potassium permanganate *(b)*. Arbitrary concentrations, read versus water as a blank. *(Beckman DB-G spectrophotometer.)*

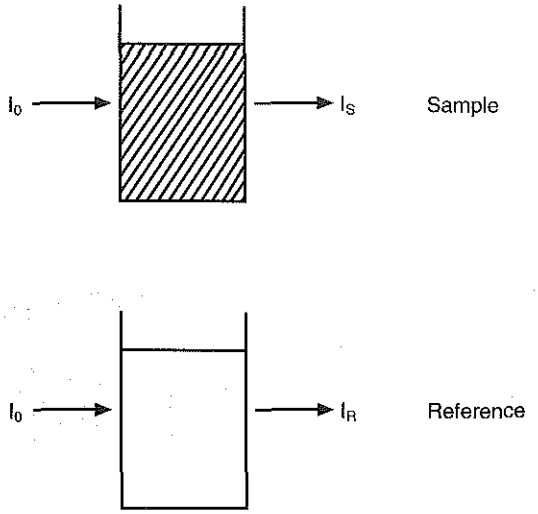

Figure 3-2 Transmittance of light through sample and reference cells. Transmittance of sample versus reference $= \frac{I_S}{I_R}$. I_0 = intensity of incident light; I_S = intensity of transmitted light for compound in solution; I_R = intensity of transmitted light through reference cell.

TABLE 3-1 Ultraviolet, Visible, and Short Infrared Spectrum Characteristics

Wavelength (nm)	Region Name	Color Observed*
<380	Ultraviolet†	Invisible
380-440	Visible	Violet
440-500	Visible	Blue
500-580	Visible	Green
580-600	Visible	Yellow
600-620	Visible	Orange
620-750	Visible	Red
800-2500	Near-infrared	Not visible
2500-15,000	Mid-infrared	Not visible
15,000-1,000,000	Far-infrared	Not visible

*Owing to the subjective nature of color, the wavelength intervals shown are only approximations.
†The ultraviolet (UV) portion of the spectrum is sometimes further divided into "near" UV (200-380 nm) and "far" UV (<220 nm). This arbitrary distinction has a practical basis, because silica used to make cuvets transmits light effectively at wavelengths ≥220 nm.

SPECTROPHOTOMETRY

Photometry is defined as the measurement of light; *spectrophotometry* is defined as the measurement of the intensity of light at selected wavelengths. Spectrophotometric analysis is a widely used method of quantitative and qualitative analysis in the chemical and biological sciences; it is accurate and sensitive. The method depends on the light absorbing properties of either the substance or a derivative of the substance being analyzed. The intensity of transmitted light passing through a solution containing an absorbing substance (chromogen) is decreased by the absorbed fraction. This fraction is then detected, measured, and used to relate the light transmitted or absorbed to concentration of the analyte in question.

Basic Concepts

Consider an incident light beam with intensity I_0 passing through a square cell containing a solution of a compound that absorbs light of a certain wavelength, λ (Figure 3-2). Given that the intensity of the transmitted light beam I_S is less than I_0, the transmittance (T) of light is defined as:

$$T = \frac{I_S}{I_0} \tag{4}$$

A portion of the incident light, however, may be reflected by the surface of the cell or absorbed by the cell wall or solvent. To focus attention on the compound of interest, elimination of these factors is necessary. This is achieved using a reference cell identical to the sample cell, except that the compound of interest is omitted from the solvent in the reference cell. The transmittance (T) through this reference cell is I_R divided by I_0; the transmittance for the compound in solution then is defined as I_S divided by I_R. In practice the reference cell is inserted and the instrument adjusted to an arbitrary scale reading of 100 (corresponding to 100% transmittance), after which the percent transmittance reading is made on the sample. As we increase the concentration of the compound in solution, we find that transmittance varies inversely and logarithmically with concentration. Consequently, it is more convenient to define a new term, absorbance (A), that will be directly proportional to con-

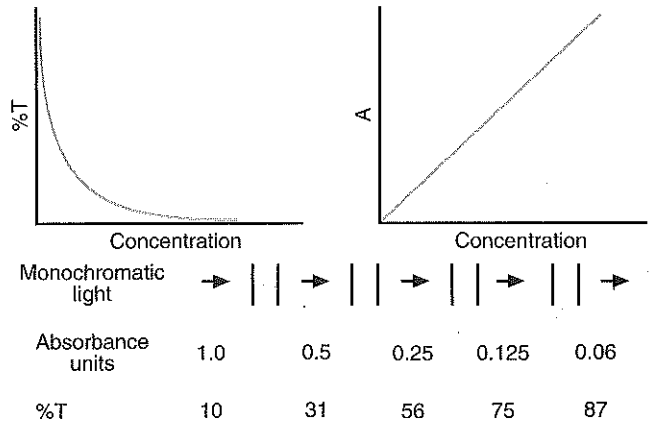

Figure 3-3 Absorbance and %T relationship.

centration. Thus the amount of light absorbed (A) as the incident light passes through the sample is equivalent to

$$A = -\log\frac{I_S}{I_R} = -\log T \tag{5}$$

Analytically, the amount of light absorbed or transmitted is related mathematically to the concentration of the analyte in question by Beer's law.

Beer's Law—Relationship between Transmittance, Absorbance, and Concentration

Beer's law (also known as the Beer-Lambert law) states that the concentration of a substance is directly proportional to the amount of light absorbed or inversely proportional to the logarithm of the transmitted light (Figure 3-3). Mathematically, Beer's law is expressed as

$$A = abc \tag{6}$$

where

A = Absorbance
a = Proportionality constant defined as absorptivity
b = Light path in centimeters
c = Concentration of the absorbing compound, usually expressed in grams per liter

This equation forms the basis of quantitative analysis by absorption photometry. When b is 1 cm and c is expressed in moles per liter, the symbol ε is substituted for the constant a. The value for ε is a constant for a given compound at a given wavelength under prescribed conditions of solvent, temperature, pH, etc., and is called the molar absorptivity. The nomenclature of spectrophotometry is summarized in Table 3-2. Values for ε are useful to characterize compounds, establish their purity, and compare sensitivities of measurements obtained on derivatives. Pure bilirubin, for example, when dissolved in chloroform at 25 °C, has a molar absorptivity of 60,700 ± 1600 at 453 nm. The molecular weight of bilirubin is 584. Hence a solution containing 5 mg/L (0.005 g/L) should have an absorbance of

$$A = (60{,}700) \times (1) \times (0.005/584) = 0.520$$

TABLE 3-2 Spectrophotometry Nomenclature

Name	Symbol	Definition
Absorbance	A	$\log T$ or $\log I_0/I$
Absorptivity	a	A/bc (c in g/L)
Molar absorptivity	ε	A/bc (c in mol/L)
Path length	b	Internal cell or sample length, in cm
Transmittance	T	I/I_0*
Wavelength unit	nm	10^{-9} m
Absorption maximum	λmax	Wavelength at which a maximum absorption occurs

*I/I_0 is the ratio of the intensity of transmitted light to incident light.

The molar absorptivity of the complex between ferrous iron and *s*-tripyridyltriazine is 22 600, whereas that with 1,10-phenanthroline is 11 000. Thus for a given concentration of iron, *s*-tripyridyltriazine produces a complex with an absorbance about twice that of the complex with 1,10-phenanthroline. Consequently, *s*-tripyridyltriazine is a more sensitive reagent to use in the measurement of iron.

Application of Beer's Law

In practice, the direct proportionality between absorbance and concentration must be established experimentally for a given instrument under specified conditions. Frequently a linear relationship exists up to a certain concentration or absorbance. When this relationship occurs, the solution is said to obey Beer's law up to this point. Within this limitation, a calibration constant (K) may be derived and used to calculate the concentration of an unknown solution by comparison with a calibrating solution. Rearranging equation (6) gives:

$$a = \frac{A}{bc} \tag{7}$$

Therefore

$$\frac{A_1}{b_1c_1} = \frac{A_2}{b_2c_2} \tag{8}$$

Because the light path (b) remains constant in a given method of analysis with a fixed cuvet size ($b_1 = b_2$), Equation (8) then becomes

$$\frac{A_1}{c_1} = \frac{A_2}{c_2} \quad \text{or} \quad \frac{A_c}{c_c} = \frac{A_u}{c_u} \tag{9}$$

where subscripts c and u indicate the absorbance (A) and concentration (c) of calibrating and unknown solutions, respectively.

Solving for the concentration of unknown

$$c_u = \frac{A_u}{A_c} \times c_c \tag{10}$$

or the equivalent expression

$$c_u = A_u \times \frac{c_c}{A_c} = A_u K \tag{11}$$

where $K = \frac{c_c}{A_c}$. The value of the constant K is obtained through measurement of the absorbance (A_c) of a calibrator of known concentration (c_c).

Certain precautions must be observed with the use of such calibration constants. Under no circumstances should the constant be used when either the calibrator or unknown readings exceed the linear portion of the calibration curve, a condition when the curve no longer obeys Beer's law. At least two and preferably more calibrators should be included in each series of determinations to permit direct comparison of unknown with calibrator or to calculate the calibration constant because variations in reagents, working conditions, cell diameters, and deterioration or changes in instruments may result in day-to-day changes of the absorbance value for the calibrator. A nonlinear calibration curve may be used if a sufficient number of calibrators of varying concentrations is included to cover the entire range encountered for readings on unknowns.

In some cases a pure reference material may not be readily available, and constants may be provided that were obtained on pure materials and reported in the literature. In general, published constants should be used only if the method is followed in detail and readings are made on a spectrophotometer capable of providing light of high spectral purity at a verified wavelength. Use of broader-band light sources usually leads to some decrease in absorbance. The absorbance of NADH at 340 nm, for example, frequently is used as a reference for the determination of enzyme activity, based on a molar absorptivity of 6.22×10^3 (see Chapter 8). This value is acceptable only under the carefully controlled conditions previously described and should not be used unless these conditions are met. Published values for molar absorptivities and absorption coefficients should be used only as guidelines until they are verified by readings on pure reference materials for a given instrument. In addition, Beer's law is followed only if the following conditions are met:

- Incident radiation on the substance of interest is monochromatic.
- The solvent absorption is insignificant compared with the solute absorbance.
- The solute concentration is within given limits.
- An optical interferant is not present.
- A chemical reaction does not occur between the molecule of interest and another solute or solvent molecule.

Instrumentation

Modern instruments isolate a narrow wavelength range of the spectrum for measurements. Those that use filters for this purpose are referred to as *filter photometers;* those that use prisms or gratings are called *spectrophotometers.* Spectrophotometers are classified as being either single or double-beam.

The major components of a *single-beam spectrophotometer* are shown schematically in Figure 3-4. In such an instrument, a beam of light is passed through a monochromator that isolates the desired region of the spectrum to be used for measurements. Slits are used to isolate a narrow beam of the light and improve its chromatic purity. The light next passes through an absorption cell (cuvet), where a portion of the radiant energy is absorbed, depending on the nature and concentration of the substance in the solution. Any light not absorbed is transmitted to a detector (photocell or phototube), which converts light energy to electrical energy that can be registered on a meter or recorder or digitally displayed.

In operation, an opaque block is substituted for the cuvet, so that no light reaches the photocell, and the meter is adjusted to read 0% *T.* Next a cuvet containing a reagent blank is inserted and the meter is adjusted to read 100% *T* (zero absorbance). The composition of the reagent blank should be identical to that of calibrating or unknown solutions except for the substance to be measured. Calibrating solutions containing various known concentrations of the substance are inserted, and readings are recorded. Finally, a reading is made of the unknown solution, and its concentration is determined by comparison with the readings obtained on the calibrators. In most spectrophotometers, digital hardware and software are integral components and perform these functions automatically.

Figure 3-5 illustrates schematically a typical double-beam-in-space system in which all components are duplicated except the light source. Another approach is a double-beam-in-time instrument that uses a light-beam chopper (a rotating wheel with alternate silvered sections and cutout sections) inserted after the exit slit (Figure 3-6). A system of mirrors passes the portions of the light reflected

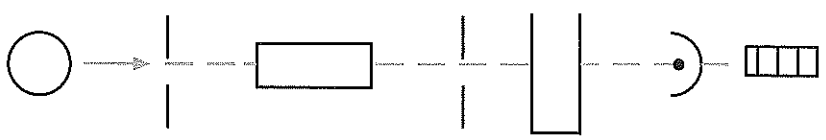

Figure 3-4 Major components of a single-beam spectrophotometer.

off the chopper alternately through the sample and a reference cuvet onto a common detector. The chopped-beam approach, using one detector, compensates for light source variation and for sensitivity changes of the detector.

Components

The basic components of a spectrophotometer include (1) a light source; (2) a means to isolate light of a desired wavelength; (3) fiber optics; (4) cuvets; (5) a photodetector; (6) a readout device; (7) a recorder; and (8) a microprocessor.

Light Sources

Types of light sources used in spectrophotometers include incandescent lamps and lasers.

Incandescent Lamps. The light source for measurements in the visible portion of the spectrum is usually a tungsten light bulb. The lifetime of a tungsten filament is greatly increased by the presence of a low pressure of iodine or bromine vapor within the lamp. An example is the *quartz-halogen* lamp, which has a fused-silica envelope and which provides high-intensity light over a wide spectrum and for extended operating periods (2000 to 5000 hours before replacement is necessary). The tungsten lamp is acceptable for making measurements of moderately dilute solutions in which the change in absorbance varies significantly with small changes in concentration.

A tungsten light source does not supply sufficient radiant energy for measurements below 320 nm. In the UV region of the spectrum, a low-pressure mercury-vapor lamp that emits a discontinuous or line spectrum is useful for calibration purposes but is not very practical for absorbance measurements, because it can be used only at certain wavelengths. Hydrogen and deuterium lamps provide sources of continuous spectra in the UV region with some sharp emission

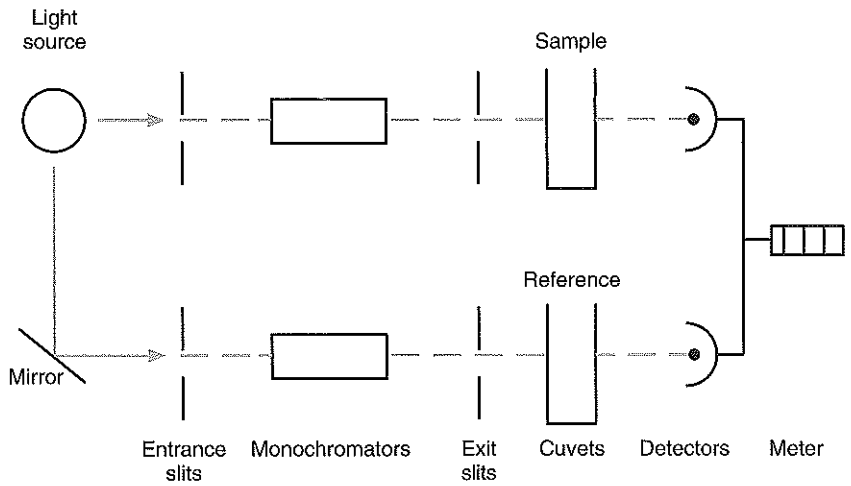

Figure 3-5 Double-beam-in-space spectrophotometer.

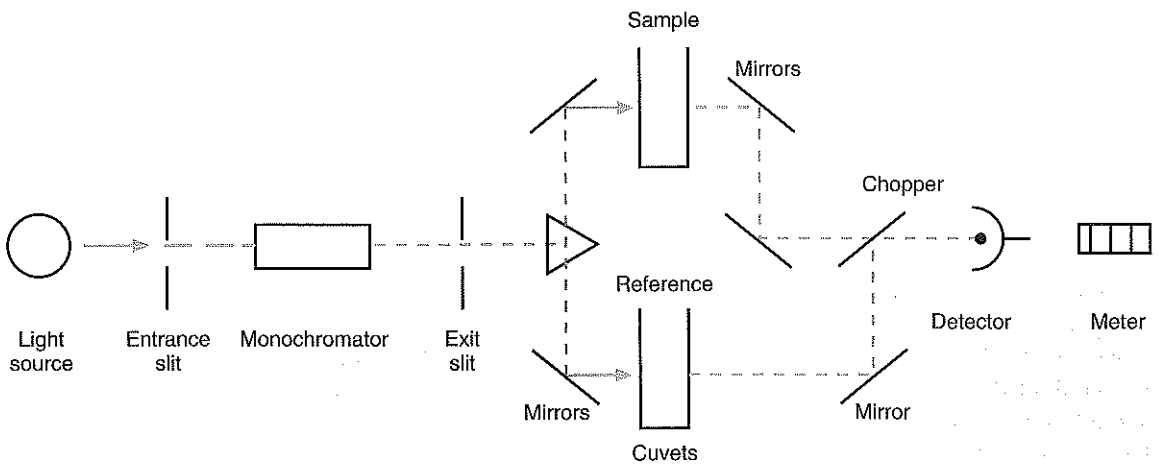

Figure 3-6 Double-beam-in-time spectrophotometer.

lines, as do high-pressure mercury and xenon arc lamps. These sources are more commonly used in UV absorption measurements. A deuterium lamp is more stable and has a longer life than a hydrogen lamp.

A widely used photometer used as a high-pressure liquid chromatographic (HPLC) detector uses the intense 254-nm resonance line produced by a mercury arc lamp (see Chapter 6). Others employ a miniature hollow cathode lamp as a very-narrow-wavelength intense source. For example, a zinc hollow cathode lamp gives a line at 214 nm that is adequately close to the maximum wavelength of peptide bond absorption (206 nm) so that it can be used to measure peptides and proteins. Details on the hollow cathode lamp are found in the section on Atomic Absorption Spectrophotometry. The hollow cathode lamp also has a long, useful lifetime if a lower-current, nonpulsed power supply is used.

Laser Sources. A laser (light amplification by stimulated emission of radiation) is a device that controls the way that energized atoms release photons; they are used as light sources in spectrophotometers as they provide intense light of a narrow wavelength. These devices are based on certain materials having the capability of absorbing energy and storing all or part of it. If the loss of absorbed energy is forbidden by quantum mechanical rules, the material will remain in an excited state. The delayed and slow release of energy from such materials in some cases may be called phosphorescence. If this excited material has more energy pumped into it, either at the phosphorescence wavelength or by electrical energy pumping, then there may be a rapid decay to lower energy with the emission of highly quantified light. Because of kinetic mechanisms of decay to lower energy, a highly coherent beam of light that has minimum scatter and is nearly monochromatic is produced. By selection of different materials, different wavelength(s) of light are emitted by different types of lasers (Table 3-3).

Three properties of laser sources distinguish them from "conventional" sources: (1) spatial coherence is a property of lasers that allows beam diameters in the range of several microns; (2) lasers produce monochromatic light; and (3) lasers have pulse widths that vary from microseconds (flash lamp-pulsed lasers) to nanoseconds (nitrogen lasers) to picoseconds or less (mode-locked lasers) in duration. Air-cooled argon ion lasers produce about 25 mW of energy output at 488 nm and have plasma tube lifetimes of 6000 hours or more. Continuous-wave dye lasers typically use an argon ion laser with an output of 1 W or less as an energy pump and use different fluorescent dyes to achieve excitation wavelength ranges of 400 to 800 nm. Helium-neon and helium-cadmium lasers are useful because of their low cost and ease of operation and because they emit a number of excitation wavelengths, but for helium-neon lasers power output has been limited to about 2 mW at 594 nm.

Infrared diode lasers are used in compact disc players and laser printers, and in bar code readers (see Chapter 11). They are solid-state devices, typically constructed of gallium arsenide, and energy is pumped into them at a low potential of ~1.5 V. Depending on its construction, the wavelength output of the laser ranges from 550 to 1810 nm. The development of inexpensive near-IR lasers has led to interest in using reflective techniques in the near-IR region of the spectrum (0.8 to 2.5 μm wavelength) for noninvasive monitoring of glucose. With this technique, a near-IR light source is focused on the skin of a patient. By measuring the relative absorbance differences at several lines of the near-IR spectrum—by computer subtraction of blank signals and by computer-mathematical enhancement of the signal-to-noise ratios (Fourier transform)—it is possible to measure the glucose concentration of the patient.[22]

TABLE 3-3 Various Types of Lasers and the Wavelengths at which They Operate

Laser	Wavelength(s) (nm)
Argon fluoride	193
Argon fluoride	248
Helium-cadmium	325 or 442
Nitrogen	337
Argon (blue)	488
Argon (green)	514
Helium-neon (green)	543
Light emitting diode—GaP	550 or 700
Rhodamine 6G dye (tunable)	570-650
Laser diode (AlGaInP, GaAlAs)	633-1,660
Helium-neon (red)	633
Ruby ($CrAlO_3$) (red)	694
Light emitting diode—GaAs	880
Light emitting diode—Si	1100
Neodymium-YAG (yttrium aluminum garnet)	1064
Carbon dioxide	9300, 9600, 10,300, or 10,600

Spectral Isolation

A system for isolating radiant energy of a desired wavelength and excluding that of other wavelengths is called a *monochromator.* There are various ways of accomplishing this, including the use of filters, prisms, and diffraction gratings. Combinations of lenses and slits may be inserted before or after the monochromatic device to render light rays parallel or to isolate narrow portions of the light beam. Variable slits may be used to permit adjustments in total radiant energy reaching the photocell.

Filters. The simplest type of filter is a thin layer of colored glass. Certain metal complexes or salts, dissolved or suspended in glass, produce colors corresponding to the predominant wavelengths transmitted. Strictly speaking, a glass filter is not a true monochromator because it transmits light over a relatively wide range of wavelengths. The spectral

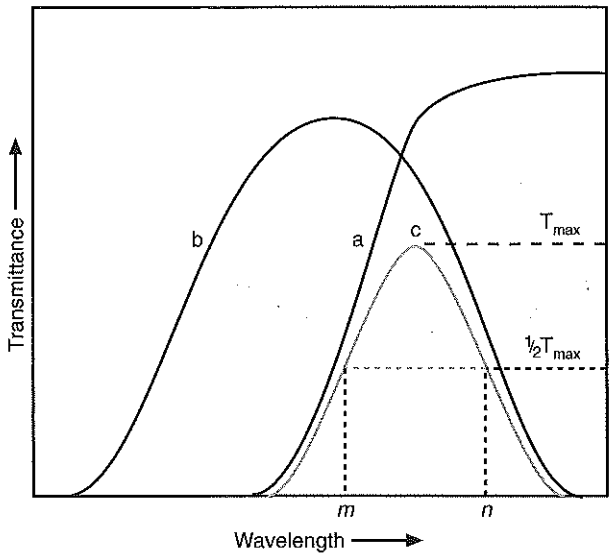

Figure 3-7 Spectral characteristics of a sharp-cutoff filter *(a)* and a wide-bandpass filter *(b)*. The narrow-bandpass filter *(c)* is obtained by combining filters *a* and *b*. The spectral bandwidth of filter *c* (distance *n-m*) is defined as the width in nanometers of the spectral transmittance curve at a point equal to one half of maximum transmittance.

purity of a filter or other monochromator is usually described in terms of its *spectral bandwidth*. This is defined as the width, in nanometers, of the spectral transmittance curve at a point equal to one half the peak transmittance (Figure 3-7). Commonly used glass filters have spectral bandwidths of approximately 50 nm and are referred to as *wide-bandpass filters*.

Other glass filters include the narrow-bandpass and sharp-cutoff types (see Figure 3-7). As shown, a cutoff filter typically shows a sharp rise in transmittance over a narrow portion of the spectrum and is used to eliminate light below a given wavelength. Narrow-bandpass filters may be constructed by combining two or more sharp-cutoff filters or regular filters; however, the availability of high-intensity light sources now favors the use of narrow-bandpass interference filters.

Another approach for construction of narrow-bandpass filters is to use a dielectric material of controlled thickness sandwiched between two thinly silvered pieces of glass. The thickness of the layer determines the wavelength of energy transmitted. These filters have narrow spectral bandwidths, usually from 5 to 15 nm, and are referred to as *interference filters*. Because they also transmit harmonics, or multiples, of the desired wavelength, accessory glass filters are required to eliminate these undesired wavelengths. Thus an interference filter designed for 620 nm will also transmit some radiation at 310 and 1240 nm unless accessory cutoff filters are provided to absorb this undesired stray light.

Prisms and Gratings. Prisms and diffraction gratings are also widely used as monochromators. A *prism* separates white light into a continuous spectrum by refraction with shorter wavelengths being bent, or refracted, more than longer wavelengths as they pass through the prism. A *diffraction grating* is prepared by depositing a thin layer of aluminum-copper alloy on the surface of a flat glass plate, then ruling many small parallel grooves into the metal coating. Better gratings contain 1000 to 2000 lines/mm and must be made with great care. These are then used as molds to prepare less expensive replicas for general use in instruments.

Modern holographic gratings are made using a laser in a "high-precision machining" mode. The focused beam of the laser is accurately scanned over a photosensitive material termed a "photoresist." After multiple lines have been scribed on the photoresist, chemicals are used to dissolve and elute the exposed photoresist to create the channels that become the lines of the grating. A layer of a highly reflective material is then sputtered onto the surface of the laser-etched channels, and the grating is ready for use. Either a flat photoresistive surface or a concave surface can be used to make this type of grating. These types of gratings are extremely accurate, have low light scatter, and are widely used in the spectrophotometers used in clinical chemistry instruments. For example, most UV-visible spectrophotometers and virtually all IR spectrophotometers use reflective gratings. In addition, HPLC detectors frequently use a concave holographic reflective grating in their optical system.

Each line ruled on the grating, when illuminated, gives rise to a tiny spectrum. Wave fronts are formed that reinforce those wavelengths in phase and cancel those not in phase. The net result is a uniform linear spectrum. Some instruments contain diffraction gratings that produce spectral bandwidths of 20 nm or more; higher-priced instruments may have a resolution of 0.5 nm or less.

The flat surface grating discussed above is called a plane *transmission grating*. Lines are engraved on the surface of a mirror, which may be either a polished metal slab or a glass plate on which a thin, metallic film has been deposited. A grating may also be ruled at a specified angle, so that a maximum fraction of the radiant energy is directed into wavelengths diffracted at a selected angle. This type of grating is called an *echelette* and is said to have been given a *blaze* at a particular angle or to have been blazed at a certain wavelength (e.g., 250 nm).

Selection of a Monochromator. The type of monochromator chosen depends on the analytical purpose for which it is to be used. For example, narrow-bandpass filters are typically used in flame photometry to isolate emission energy at a given wavelength. Alternately, narrow spectral bandwidths are required in spectrophotometers for resolving and identifying sharp absorption peaks that are closely adjacent. Lack of agreement with Beer's law will occur when a part of the spectral energy transmitted by the monochromator is not absorbed by the substance being measured. This is more commonly observed with wide-bandpass instruments.

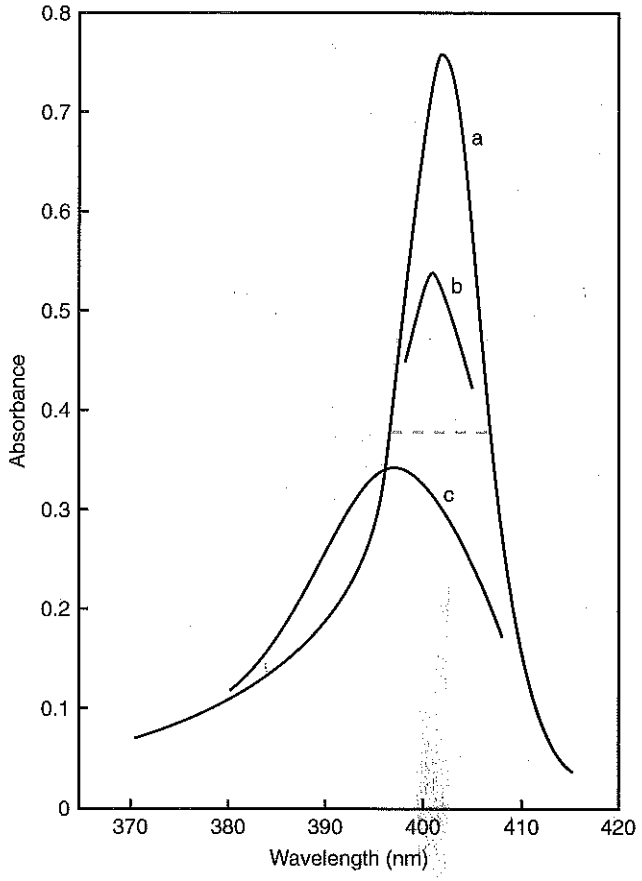

Figure 3-8 Effect of spectral bandwidth (SBW) on the absorption spectrum of coproporphyrin I. Nominal concentration, 1 μg/mL in HCl, 0.1 mol/L. SBW: *curve a,* 1 nm, Beckman DB-G spectrophotometer; *curve b,* 10 nm; and *curve c,* 20 nm, Beckman DB spectrophotometer. The *dotted horizontal line* shows a natural bandwidth of 10 nm for coproporphyrin I when scanned at a spectral bandwidth of 1 nm. The shift of A_{max} to lower wavelengths as SBW is increased is related to skewness of the absorption spectrum to the left.

Some increase in absorbance and improved linearity with concentration is usually observed with instruments that operate at narrower bandwidths of light. This is especially true for substances that exhibit a sharp peak of absorption. Spectral absorbance curves for a solution of coproporphyrin I (Figure 3-8) demonstrate the marked decrease in maximum absorbance as the spectral bandwidth is increased from 1 to 20 nm. The *natural bandwidth* of an absorbing substance is defined as "the bandwidth of the spectral absorbance curve at a point equal to one half of the maximum absorbance." Curve A in Figure 3-8, scanned at a *spectral* bandwidth of 1 nm, shows a *natural* bandwidth of approximately 10 nm. As a general rule, for peak absorbance readings to be within 99.5% of true values, the spectral bandwidth should not exceed 10% of the natural bandwidth. For example, many chemistry procedures used in the clinical laboratory produce an absorbing species for which the natural bandwidth ranges from 40 to over 200 nm. The natural bandwidth of NADH is 58 nm ($\lambda max = 339$ nm). Therefore, for accurate measurements of this compound, we should use a spectral bandwidth of 6 nm or less. Actual studies have shown that use of a 10-nm spectral bandwidth at 340 nm produces absorbance values approximately 98% of those obtained with a 1-nm spectral bandwidth.

In practice, the wavelength selected is usually at the peak of maximum absorbance to achieve maximum sensitivity; however, it may be desirable to choose another wavelength to minimize interfering substances. For example, turbidity readings on a spectrophotometer are greater in the blue region than in the red region of the spectrum, but the latter region is chosen for turbidity measurements to avoid absorption of light by bilirubin (460 nm) or hemoglobin (417 and 575 nm). The absorbing species developed in the alkaline picrate procedure for creatinine produces a relatively flat peak in the visible region of the spectrum at approximately 480 nm, but the reagent blank itself absorbs light strongly below 500 nm. A compromise is made by selecting a wavelength at 520 nm to minimize the contribution of the blank. Blank readings should, of course, be kept to a minimum. A small difference between two large numbers is subject to greater uncertainty; hence minimizing absorbance of the blank improves precision and accuracy. The linear working range of a method can be expanded also by not measuring at the peak absorbance. However, measurements should not be taken on the steep slope of an absorption curve, because a slight error in wavelength adjustment would introduce a significant error in absorbance readings.

Fiber Optics

In the single- and double-beam spectrophotometers shown diagrammatically in Figures 3-4 through 3-6, the positioning of the individual components dictates the path that the light beam must follow as it travels from the source to the detector. This approach places certain restrictions on the design, size, and cost of such instruments. To overcome these restrictions, fiber optics are now integrated into the optical design of spectrophotometers.[15] Fiber optics, also known as *light pipes,* are bundles of thin, transparent fibers of glass, quartz, or plastic that are enclosed in material of a lower index of refraction and that transmit light throughout their lengths by internal reflections. The use of fiber optics in spectrophotometers offers the advantage of better directional control of the beam of light within the geometrical confines of an instrument; this allows for the design and manufacture of miniature and inexpensive optical subsystems for use in automated instruments. For example, a single light source can be multiplexed with multiple detectors by fiber optics for optimal positioning of the source and detectors in an automated system (see Chapter 11). Disadvantages of fiber optics include greater amounts of stray light; refractive index changes in the glass, quartz, or plastic rods; and the loss of transmitted energy after continued use in the UV region of the spectrum. This loss of energy is known as solar-

ization and results in a decrease in the optical sensitivity of an instrument.

Cuvets

A cuvet (also often termed a cuvette) is a small vessel used to hold a liquid sample to be analyzed in the light path of a spectrometer. Cuvets may be round, square, or rectangular and are constructed from glass, silica (quartz), or plastic. Square or rectangular cuvets have plane-parallel optical surfaces and a constant light path. The most popular have a 1.0-cm light path, held to close tolerances. Ordinary borosilicate glass cuvets are suitable for measurements in the visible portion of the spectrum. For readings below 340 nm, however, quartz cells are usually required. Some plastic cells have good clarity in both the visible and UV range but can present problems relating to tolerances, cleaning, etching by solvents, and temperature deformations. Many of the plastic cuvets are designed for disposable, single-use applications.

Cuvets must be clean and optically clear, as etching or deposits on the surface affect absorbance values. Cuvets used in the visible range are cleaned by copious rinsing with tap water and distilled water. Alkaline solutions should not be left standing in cuvets for prolonged periods, because alkali slowly dissolves glass and produces etching. Cuvets may be cleaned in mild detergent or soaked in a mixture of concentrated HCl:water:ethanol (1:3:4). Cuvets should never be soaked in dichromate cleaning solution, because the solution is hazardous and tends to adsorb onto and discolor the glass.

Cuvets used for measurements in the UV region should be handled with special care. Invisible scratches, fingerprints, or residual traces of previously measured substances may be present and absorb significantly. A good practice is to fill all such cuvets with distilled water and measure the absorbance for each against a reference blank over the wavelengths to be used. This value should be essentially zero.

Photodetectors

Photodetectors are devices that convert light into an electric signal that is proportional to the number of photons striking its photosensitive surface. The photomultiplier tube is a commonly used photodetector for measuring light intensity in the UV and visible regions of the spectrum. Photodiodes are solid-state devices that are also used in modern instruments. In older instruments, barrier layer cells (also known as photovoltaic cells) were used as photodetectors, because they were rugged and less expensive.[5]

Photomultiplier Tubes. A photomultiplier tube (PMT) contains a cathode, a light-sensitive metal, and a series of dynodes all of which are enclosed in an evacuated glass enclosure. As many as 10 to 15 stages or dynodes are present in common photomultipliers. Photons that strike the photoemissive cathode emit electrons that are accelerated toward the dynodes. Additional electrons are generated at each dynode. This cascading effect creates 10^5 to 10^7 electrons for each photon hitting the first cathode depending on the number of dynodes and the accelerating voltage. This amplified signal is finally collected at the anode where it can be measured.

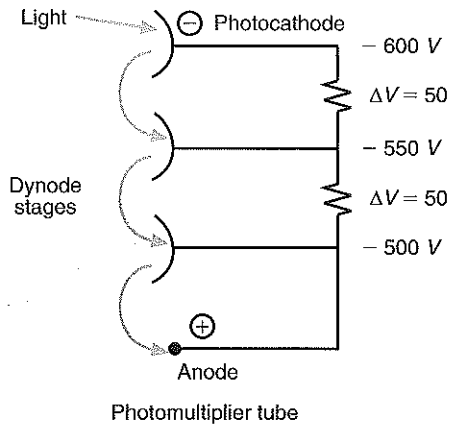

Figure 3-9 Schematic diagrams of a glass photomultiplier tube.

When operating such a tube, voltage is applied between the photocathode and each successive stage. The normal increment of voltage increase of each photomultiplier stage is from 50 to 100 V larger than that of the previous stage (Figure 3-9). Typically, a conventional PMT tube has approximately 1500 V applied to it.

PMTs have extremely rapid response times, are very sensitive, and are slow to fatigue. Because these tubes have excellent sensitivity and rapid response, they must be carefully shielded from all stray light and daylight. A PMT with the voltage applied should never be exposed to room light because it will burn out. Because of the fast response time of the PMT, this detector is readily used with interrupted light beams such as those produced by choppers, and it therefore has significant advantages when used as a UV-visible detector in spectrophotometers. The rapid response times are needed when a spectrophotometer is being used to determine an absorption spectrum of a compound. PMTs also have adequate sensitivity over a wide range of wavelengths.

When voltage is applied to a PMT in the absence of any incident light, some current is usually produced. This current is called *dark current.* It is desirable to have the dark current of a PMT at its lowest level because this current is also amplified and appears as background noise.

Photodiodes. Photodiodes are solid-state photodetectors that are fabricated from photosensitive semiconductor materials such as silicon, gallium arsenide, indium antimonide, indium arsenide, lead selenide, and lead sulfide. These materials absorb light over a characteristic wavelength range (e.g., 250 nm to 1100 nm for silicon). Their development and use as detectors in spectrophotometers have resulted in instruments capable of measuring light at a multitude of wavelengths. When a photodetector consists of two-dimensional arrays of diodes, each of which responds to a specific wavelength, it is known as photodiode array. For

example, photodiode arrays have been designed to have a 2-nm resolution per diode from 200 to 340 nm, and a 1-nm resolution per diode from 340 to 800 nm.

In practice, all diodes are initially charged to 5 V, and they discharge when they are struck by light. Each diode is then sequentially scanned and recharged to 5 V. The amount of energy required for recharging is proportional to the quantity of light striking that diode. Because scan time for all diodes is in the millisecond range, many scans can be taken. The resultant data can be processed using a variety of algorithms, including signal averaging, background subtraction, and correction for scattered light. Consequently, an optical spectrum of an ongoing chemical reaction can be monitored as a function of time with a high degree of resolution and accuracy.

Readout Devices

Electrical energy from a detector is displayed on some type of meter or readout system. In the past analog devices were widely used as readout devices in spectrophotometers. However, they have been replaced by digital readout devices that provide a visual numerical display of absorbance or converted values of concentrations. These operate on the principle of selective illumination of portions of a bank of light-emitting diodes (LEDs), controlled by the voltage signal generated. Visible LEDs incorporate gallium as the major component, and at present, $GaAs_xP_x$ diodes that emit red light are most widely used. Compared with meters, the digital readout devices have faster response and are easier to read.

Microprocessors

Microprocessors are incorporated into both photometers and spectrophotometers. With a resident microprocessor and software, output from a calibrator is digitally stored, digital signals from blanks are subtracted from calibrators and unknowns, and the concentration of unknowns automatically calculated. Data from multiple calibrators may be used to store a complete calibration curve, display or print out the curve for visible inspection, and calculate results of unknowns based on the curve or some mathematical transformation of the data. A microprocessor and its resident software are also used to convert kinetic data into concentration or enzyme activity.

Recorders

Spectrophotometers may be equipped with recorders in addition to or instead of a digital display. These are synchronized to provide line traces of transmittance or absorbance as a function of either time or wavelength. When a continuous tracing of absorbance versus wavelength is recorded, the resultant figure is called an *absorption spectrum.* If a substance absorbs light, distinct peaks of absorbance will be observed (see Figure 3-1). Measuring the absorption spectra of an unknown sample and comparing them with spectra from known compounds is very useful for qualitative purposes. For example, this type of procedure is especially useful for identification of drugs that absorb in the UV region. Several criteria are used, including determination of those wavelengths showing maximum and minimum absorbance in both dilute acid and alkaline solutions; absorptivity at the wavelength of maximum absorbance; and ratios of absorbance at two wavelengths. Finally, the entire spectrum is compared with that of a known sample of the suspected drug.

Performance Parameters

In most spectrophotometric analytical procedures, the absorbance of an unknown is compared directly with that of a calibrator or series of calibrators. Under these circumstances, minor errors in wavelength calibration, variation in spectral bandwidths, or presence of stray light are compensated for and do not usually contribute serious errors. Use of a series of calibrators covering a wide range of concentrations also provides a measure of linearity (i.e., agreement with Beer's law for a given procedure and instrument). When calculations are based on published or previously determined values for molar absorptivities or absorption coefficients, however, the spectrophotometer must be checked more rigorously. Performance verification of spectrophotometers on a periodic basis also improves reliability of routine comparative analyses.

To verify that a spectrophotometer is performing satisfactorily, the device must be shown to be able to operate within the specifications provided for it. Parameters to be tested include (1) wavelength accuracy, (2) spectral bandwidth, (3) stray light, (4) linearity, and (5) photometric accuracy.

The National Institute of Standards and Technology (NIST), formerly the National Bureau of Standards (NBS), provides several standard reference materials (SRMs) for spectrophotometry that are useful in the calibration or verification of the performance of photometers or spectrophotometers (e.g., SRM 930e is for the verification and calibration of the transmittance and absorbance scales of visible absorption spectrometers) (see http://www.nist.gov).

The Institute for Reference Materials and Measurements (IRMM), a metrology institute that belongs to the European Commission, also provides reference materials for verification of the performance of photometers or spectrophotometers. These materials are listed in the IRMM BCR Reference Materials Catalogue (http://www.irmm.jrc.be/).

Wavelength Calibration

For many analytical purposes, the calibration wavelength chosen may be satisfactory if it is close to the λ_{max} of the chromogen being measured and the wavelength is reproducible. Most filters fall into this category and are quite satisfactory because unknowns are compared with calibrators at a fixed wavelength and spectral bandwidth. With prisms

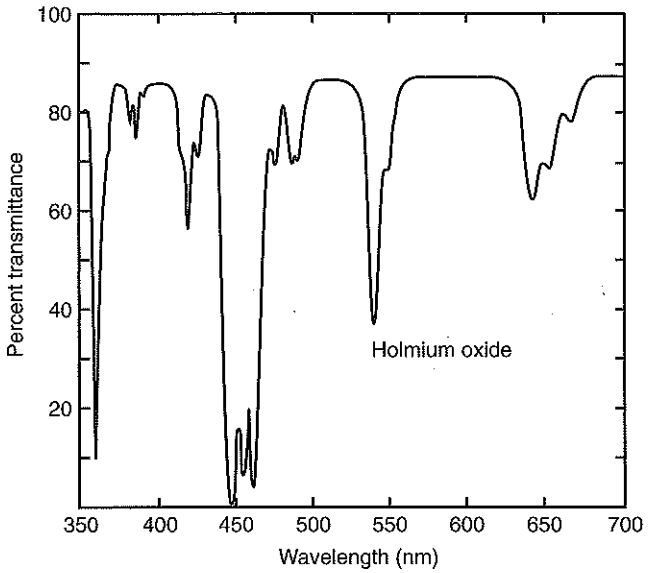

Figure 3-10 Spectral transmittance curve of holmium oxide filter.

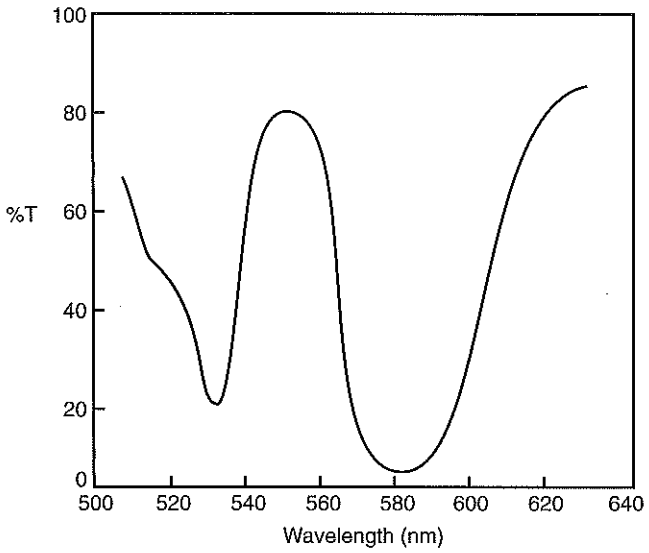

Figure 3-11 Spectral transmittance curve of a didymium filter. *(Perkin-Elmer Model 35 spectrophotometer, 8-nm nominal spectral bandwidth.)*

and diffraction gratings, however, a continuous choice of wavelengths is available, and it becomes necessary to verify their accuracy and reproducibility. Knowledge of exact wavelength becomes critical when using published molar absorptivities for identification of substances in toxicological studies and in the use of differential absorption techniques. Enzyme assays using the NAD-NADH reaction, for example, are based on a molar absorptivity constant for NADH of 6.22×10^3 at 339 nm (340 nm). The wavelength settings therefore must be accurate and reproducible, and the instrument must show spectrophotometric accuracy if the constant is to be used in results calculation.

For the narrow-spectral-bandwidth instruments, a *holmium oxide glass* may be scanned over the range of 280 to 650 nm. This material shows very sharp absorbance peaks at defined wavelengths, and the operator may compare the wavelength scale readings that produce maximum absorbance with established values. Should these not coincide, a calibration curve can be constructed to relate scale readings to true wavelengths. A typical spectral transmittance curve for holmium oxide glass is shown in Figure 3-10. Selected absorption peaks for this filter, which are suitable for calibration purposes, occur at the following wavelengths: 279.3, 418.5, 287.6, 536.4, 333.8, 637.5, and 360.8 nm. Solutions of holmium oxide in dilute perchloric acid have also been recommended and may be used with any spectrophotometer.

With broader-bandpass instruments, a didymium filter may be used to verify wavelength settings. This filter should show a minimum percent transmittance at 530 nm against an air blank (Figure 3-11). Because didymium has several absorption peaks, the setting should be verified grossly by visual examination of transmitted light. This light should appear green at 530 nm.

Spectral Bandwidth

The spectral bandwidth of a spectrophotometer is measured by use of a mercury-vapor lamp, which shows a number of sharp, well-defined emission lines between 250 and 580 nm. The apparent width of an emission band at half-peak height is taken to be the spectral bandwidth of the instrument (see Figure 3-7). The spectral bandwidth may also be calculated from the manufacturer's specifications. Interference filters with spectral bandwidths of 1 to 2 nm are available and may be used to check those instruments with a nominal spectral bandwidth of 8 nm or more.

Stray Light

Stray light, in general terms, is radiation of wavelengths outside the narrow band nominally transmitted by the monochromator. A perfect monochromator would transmit light only within its passband. In practice, scattering and diffraction inside the monochromator introduce light of other wavelengths into the exit beam. This light is further modified by other components of the spectrophotometer and by the sample itself. Stray light is usually defined as a ratio or percent of the stray light to the total detected light.

Other sources of unwanted light include light leaks and fluorescence of the sample. Light leaks should be excluded by covering the cell compartments. Light arising from fluorescence can increase the signal to the detector and cause an apparent decrease in absorbance. These sources of light are not included in the usual definition of stray light.

The major effect of stray light on the performance of a spectrophotometer is an absorbance error, especially in the

upper end of the absorbance range of the instrument. Most spectrophotometers are equipped with one or more stray-light filters. Thus a blue filter is used with a tungsten lamp for wavelength settings below about 400 nm. When the spectrophotometer is set to 350 nm, for example, most of the stray light is of wavelengths in the visible range. The blue filter absorbs most of the visible light but transmits well in this UV portion of the spectrum. By analogy, a red filter is used for wavelengths in the range of 650 to 800 nm.

A cutoff filter is satisfactory for the detection of stray light. These may be of glass, similar to the stray-light filters discussed previously, and produce a sharp cut in the spectrum with almost complete absorption on one side and high transmittance on the other. Liquid cutoff filters are satisfactory and convenient in the UV range where stray light is usually more of a problem. A 50 g/L aqueous solution of sodium nitrite should show essentially 0% T when read against water over the range of 300 to 385 nm. Acetone, read against water, should show 0% T over the range of 250 to 320 nm.

Linearity

For a spectrophotometer to give accurate absorbance measurements throughout its absorbance range, a linear relationship should exist between the light absorbed and the instrument readout. Various liquid solutions have been used to check instrument linearity. Several sources of error may be encountered in this type of reference material, such as dilution errors and errors from lack of stability, shifts in pH, and temperature effects. An alternative procedure is to use a solid glass filter that, at a given wavelength, has an absorbance that is a small fraction of the total linear range of the instrument. The didymium filter in Figure 3-11 has an absorbance of approximately 0.09 at 550 nm and is satisfactory for establishing linearity. Linearity is satisfactory as long as the ΔA increments remain constant. The same general procedure may be used with a suitable filter on those spectrophotometers in which the blank reference settings can be adjusted in steps up to approximately 1 unit of absorbance.

Photometric Accuracy

Solutions of potassium dichromate ($K_2Cr_2O_7$) are also used for overall checks on photometric accuracy. These also provide an indication of wavelength calibration, linearity, cuvet light path, and freedom from stray light in the UV region.

In practice, analytical reagent grade $K_2Cr_2O_7$ is dried at 110 °C for 1 hour. The following solutions in 0.005 mol/L sulfuric acid are prepared:

Solution A: 0.0500 g/L for the absorbance range from 0.2 to 0.7

Solution B: 0.1000 g/L for the absorbance range from 0.4 to 1.4

Measurements should be made in 10-mm cells with the temperature controlled in the range of 15 to 25 °C, using 0.005 mol/L sulfuric acid as the reference. Table 3-4 gives the expected values for the two absorbance maxima and minima of the solutions based on literature values. Because the natural bandwidth of solution A at 350 nm is approximately 63 nm, the values shown apply strictly to spectrophotometers with a spectral bandwidth of 6 nm or less.

Multiple-Wavelength Readings

Background interference can often be eliminated or minimized either by inclusion of blanks or by reading absorbance at two or three wavelengths. In one approach, termed "bichromatic," absorbance is measured at two wavelengths, one corresponding to peak absorbance and another at a point near the base of the peak to serve as a baseline. The difference in absorbance at the two wavelengths is related to concentration. In effect, this provides a blank reference point for each individual sample. Another method to correct for background interference is to measure absorbance at the peak wavelength and at two other wavelengths equidistant from the peak. Values for the latter are averaged to obtain a baseline under the peak, which is then subtracted from the peak reading. The value thus obtained is known as a "corrected" absorbance and can be related to the concentration, provided that the background absorbance is linear with wavelength over the region in which readings are made. This correction also must be applied to absorbances obtained from calibrators.

Before the correction is used, knowledge of the shape of the absorption curve for the substance of interest and of the interference is required. The linearity of the baseline shift should be verified by measuring the absorption spectrum of commonly encountered interferences. Care should be exercised in the use of the correction because if it is not properly used, it may introduce larger errors than would be observed without correction. For example, such a situation may occur if the background reading is not linear over the region measured.

REFLECTANCE PHOTOMETRY

In *reflectance photometry,* diffuse reflected light is measured.[5] The reflected light results from illumination, with diffused light, of a reaction mixture in a carrier or from the diffusion

TABLE 3-4 Recommended Absorbance Values for Acidic Potassium Dichromate Solutions

Wavelength (nm)	Absorbance	
	Solution A	Solution B
235 (min)	0.626 ± 0.009	1.251 ± 0.019
257 (max)	0.727 ± 0.007	1.454 ± 0.015
313 (min)	0.244 ± 0.004	0.488 ± 0.007
350 (max)	0.536 ± 0.005	1.071 ± 0.011

of light by a reaction mixture in an illuminated carrier. The intensity of the reflected light from the reagent carrier is compared with the intensity of light reflected from a reference surface. Because the intensity of reflected light is nonlinear in relation to the concentration of the analyte, either the Kubelka-Munk equation or the Clapper-Williams transformation is commonly used to convert the data into a linear format (see Chapter 11). The electro-optical components used in reflectance photometry are essentially the same as those required for absorbance photometry. Reflectance photometry is used as the measurement method with dry-film chemistry systems (see Chapter 11).

FLAME EMISSION SPECTROPHOTOMETRY

Flame emission spectrophotometry is based on the characteristic emission of light by atoms of many metallic elements when given sufficient energy, such as that supplied by a hot flame. The wavelength to be used for the measurement of an element depends on the selection of a line of sufficient intensity to provide adequate sensitivity and freedom from other interfering lines at or near the selected wavelength. For example, lithium produces a red, sodium a yellow, potassium a violet, rubidium a red, and magnesium a blue color in a flame. These colors are characteristic of the metal atoms that are present as cations in solution. Under constant and controlled conditions, the light intensity of the characteristic wavelength produced by each of the atoms is directly proportional to the number of atoms that are emitting energy, which in turn is directly proportional to the concentration of the substance of interest in the sample. Although this technique once was widely used for the analysis of sodium, potassium, and lithium in body fluids, it now has been replaced largely by electrochemical techniques.

For additional information on this technique, the reader is referred to an earlier version of this chapter.[5]

ATOMIC ABSORPTION SPECTROPHOTOMETRY

Atomic absorption (AA) spectrophotometry is used widely in clinical laboratories to measure elements such as aluminum, calcium, copper, lead, lithium, magnesium, zinc, and other metals.

Basic Concepts

Atomic absorption is an emission technique in which an element in the sample is excited and the radiant energy given off measured as the element returns to its lower energy level. However, the element is not appreciably excited in the flame, but is merely dissociated from its chemical bonds (atomized) and placed in an unexcited or ground state (neutral atom). Thus, the atom is at a low energy level in which it is capable of absorbing radiation at a very narrow bandwidth corresponding to its own line spectrum. A hollow cathode lamp with the cathode made of the material to be analyzed is used to produce a wavelength of light specific for the material. Thus, if the cathode were made of sodium, sodium light at predominantly 589 nm would be emitted by the lamp. When the light from the hollow-cathode lamp enters the flame, some of it is absorbed by the ground-state atoms in the flame, resulting in a net decrease in the intensity of the beam from the lamp. This process is referred to as *atomic absorption.*

The process is analogous to absorption spectrophotometry. For example, a specific hollow-cathode lamp serves as the light source, and the sample heated in the flame replaces the sample in the cuvet. The pathlength of the flame is analogous to the light path through the cuvet. As noted previously, only a small fraction of the sample in the flame contributes emission energy, and only a fraction of this is transmitted to the detector. Hence, most of the atoms are in the ground state and are able to absorb light emitted by the cathode lamp. In general, AA methods are approximately 100 times more sensitive than flame emission methods. In addition, owing to the unique specificity of the wavelength from the hollow-cathode lamp, these methods are highly specific for the element being measured.

Instrumentation

Figure 3-12 shows the basic components of an AA spectrophotometer. The basic component of such an instrument is the hollow-cathode lamp made of the metal of the substance to be analyzed and is different for each metal analysis. In some cases, an alloy is used to make the cathode, resulting in a multielement lamp.

The hollow-cathode lamp usually contains argon or neon gas at a pressure of a few millimeters of mercury. An argon-filled lamp produces a blue-to-purple glow during operation, and the neon produces a reddish-orange glow inside the hollow-cathode lamp. Quartz, or special glass that allows transmission of the proper wavelength, is used as a window. A current is applied between the two electrodes inside the hollow-cathode lamp, and metal is sputtered from the cathode into the gases inside the glass envelope. When

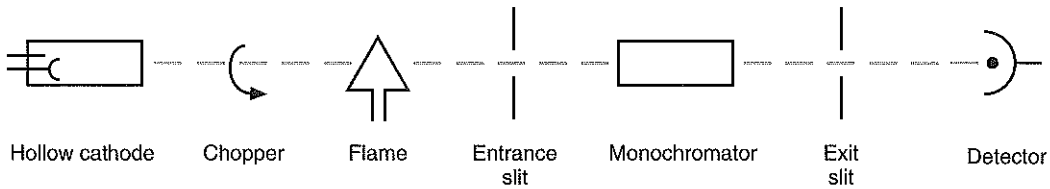

Figure 3-12 Basic components of an atomic absorption spectrophotometer.

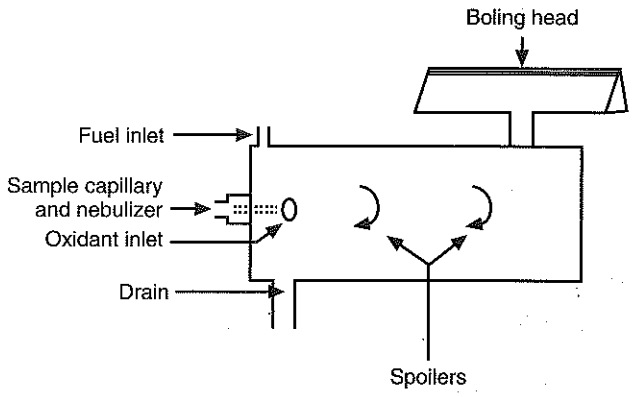

Figure 3-13 Laminar flow burner.

the metal atoms collide with the neon or argon gases, they lose energy and emit their characteristic radiation. Calcium has a sharp, intense, analytical emission line at 422.7 nm, which is most frequently used for calcium analysis. In an interference-free system, only calcium atoms absorb the calcium light from the hollow cathode as it passes through the flame.

An electric beam chopper and a tuned amplifier are incorporated into most AA instruments. Operationally, the power to the hollow-cathode lamp is pulsed so that the light is emitted by the lamp at a certain number of pulses per second. On the other hand, all of the light coming from the flame is continuous. When light leaves the flame, it is composed of pulsed, unabsorbed light from the lamp and a small amount of unpulsed flame spectrum and sample emission. The detector senses all light, but the amplifier is electrically tuned to accept only pulsed signals. In this way, the electronics in conjunction with the monochromator discriminate between the flame spectrum and sample emission.

Figure 3-13 shows a laminar flow premix burner and illustrates how the sample is aspirated, volatilized, and burned. Note that the gases are mixed and the sample is atomized before being burned. An advantage of this system is that the larger droplets go to waste while the fine mist enters the flame, thus producing a less noisy signal. In addition, the path length through the flame of the burner is longer than that of the total consumption burner. This produces a greater absorption and increases the sensitivity of the measurement. A disadvantage of the premix burner is that the flame usually is not as hot as that of the total consumption burner, and thus it cannot sufficiently dissociate certain metal complexes in the flame (e.g., calcium-phosphate complexes).

In *flameless AA* techniques (carbon rod or "graphite furnace"), the sample is placed in a depression on a carbon rod in an enclosed chamber. Strips of tantalum or platinum metal may also be used as sample cups. In successive steps, the temperature of the rod is raised to dry, char, and finally atomize the sample into the chamber. The atomized element then absorbs energy from the corresponding hollow-cathode lamp. This approach is more sensitive than the conventional flame methods and permits determination of trace metals in small samples of blood or tissue.

With flameless AA, a novel approach has been used to correct for background absorption called the Zeeman correction.[17] In Zeeman background correction, either the light source or the atomizer is placed in a strong magnetic field. In practice, because Zeeman correction requires special lamps, the analyte is placed in the magnetic field. The intense magnetic field splits the degenerate (i.e., of equal energy) atomic energy levels into two components that are polarized parallel and perpendicular to the magnetic field, respectively. The parallel component is at the resonance line of the source, whereas the two perpendicular components are shifted to different wavelengths. The two components interact differently with polarized light. A polarizer is placed between the source and the atomizer, and two absorption measurements are taken at different polarizer settings. One measures both analyte and background absorptions, A_t, the other only the background absorption, A_{bc}. The difference between the two absorption readings is the corrected absorbance.

The major advantage of the Zeeman correction method is that the same light source at the same wavelength is used to measure the total and the background absorption. The implementation is complex and expensive, and the strength of the magnetic field needs to be optimized for every element, but the method gives more accurate results at higher background levels than the other correction techniques.

Interferences in Atomic Absorption Spectrophotometry

Interferences in AA spectroscopy are divided into spectral and nonspectral interferences.

Spectral Interferences

Spectral interferences include absorption by other closely absorbing atomic species, absorption by molecular species, scattering by nonvolatile salt particles or oxides, and background emission (which can be electronically filtered). Absorption by other atomic species usually is not a problem because of the extremely narrow bandwidth (0.01 nm) used in the absorption measurements. Absorption and scattering by molecular species are particularly problematic at lower atomizing temperatures.

Nonspectral Interferences

Nonspectral interferences are either nonspecific or specific. *Nonspecific interferences* affect the nebulization by altering the viscosity, surface tension, or density of the analyte solution, and consequently the sample flow rate. Certain contaminants also decrease the desolvation and atomization efficiency by lowering the atomizer temperature. *Specific interferences* are also called chemical interferences because they are more analyte dependent. *Solute volatilization inter-*

ference refers to the situation when the contaminant forms nonvolatile species with the analyte. An example is the phosphate interference in the determination of calcium that is caused by the formation of calcium-phosphate complexes. The phosphate interference is overcome by adding a cation, usually lanthanum or strontium, that competes with calcium for the phosphate. Enhancement effects are also observed in which the addition of contaminants increases the volatilization efficiency. Such is the case with aluminum, which normally forms nonvolatile oxides but in the presence of hydrofluoric acid forms more volatile aluminum fluoride. *Dissociation interferences* affect the degree of dissociation of the analyte. Analytes that form oxides or hydroxides are especially susceptible to dissociation interferences. *Ionization interference* occurs when the presence of an easily ionized element, such as K, affects the degree of ionization of the analyte, which leads to changes in the analyte signal. In case of *excitation interference*, the analyte atoms are excited in the atomizer, with a subsequent emission at the absorption wavelength. This type of interference is more pronounced at higher temperatures.

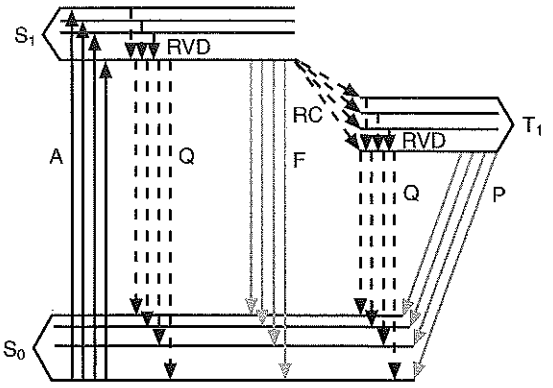

Figure 3-14 Luminescence energy-level diagram of typical organic molecule. S_0 is the ground level singlet state; S_1 is the first excited singlet state; A is the absorption process; T_1 is the first excited triplet state; and RVD is the radiationless vibrational deactivation. Q is quenching of the excited singlet or triplet state. F is the fluorescence process from the first excited singlet state. P is the phosphorescence process from the first excited triplet state. RC is the radiationless crossover from the first excited singlet state to the first excited triplet state.

FLUOROMETRY

Fluorescence occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength. An atom or molecule that fluoresces is termed a fluorophore. *Fluorometry* is defined as the measurement of the emitted fluorescence light. Fluorometric analysis is a widely used method of quantitative analysis in the chemical and biological sciences; it is accurate and very sensitive.

Basic Concepts

Figure 3-14 diagrammatically illustrates the relationship between absorption, fluorescence, and phosphorescence. As indicated, each molecule contains a series of closely spaced energy levels. Absorption of a quantum of light energy by a molecule causes the transition of an electron from the singlet ground state to one of a number of possible vibrational levels of its first singlet state. The actual number of molecules in the excited state under typical reaction conditions and excited with a typical 150-W light source is very small and is estimated to be about 10^{-13} mole per mole of fluorophore. Once the molecule is in an excited state, there are several ways it can return to its original energy state. These include radiationless vibrational equilibration, the fluorescence process, quenching of the excited singlet state, radiationless crossover to a triplet state, quenching of the first triplet state, and the phosphorescence process.

As shown in Figure 3-14, vibrational equilibration before fluorescence results in some loss of the excitation energy. The emitted fluorescence light is therefore of less energy or has a longer wavelength than the excitation light. The difference between the maximum wavelength of the excitation light and the maximum wavelength of the emitted fluorescence light is a constant referred to as the "Stokes shift." This constant is a measure of the energy lost during the lifetime of the excited state (radiationless vibrational deactivation) before return to the ground singlet level (fluorescence emission).

Time Relationships of Fluorescence Emission

The time required for a molecule to absorb radiant energy and to be promoted to an excited state is approximately 10^{-15} s. The length of time for vibrational equilibration to occur to the lowest excited state is of the order of 10^{-14} to 10^{-12} s. The length of time required for fluorescence emission to occur is of the order of 10^{-8} to 10^{-7} s. Relatively speaking, there is a considerable time delay between the absorption of light energy, the return to the lowest excited state, and the emission of fluorescence light. This time relationship is shown in Figure 3-15. Phase I in Figure 3-15 represents the time period between absorbance of light energy and radiationless loss of energy during vibrational rearrangement to the lowest excited energy state. This time period is represented by the up and down arrows in the diagram. Phase II shows the emission and decay of a short-lived (b) and a longer-lived (a) fluorophore. If the fluorescence emission is measured over time following a pulse of light from an excitation source, such as a xenon lamp or laser, the intensity of the emitted light decays as a first-order process similar to radioactive decay (i.e., phase II of Figure 3-15). The time required for the emitted light to reach 1/e of its initial intensity, where e is the Naperian base 2.718, is called the average lifetime of the excited state of the molecule, or the fluorescence decay time.

The time delay between absorption of quanta of energy and fluorescence is used in fluorescence instrumentation called time-resolved fluorometers.[9] The advantage of a time-resolved fluorometer is the elimination of background light

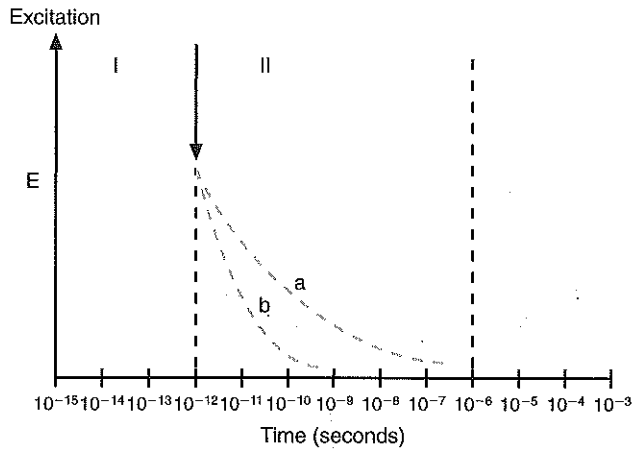

Figure 3-15 Fluorescence decay process: E is the absorption of energy; I is the vibrational deactivation time phase; II is the fluorescence emission time phase; a is long fluorescence decay time; and b is short fluorescence decay time.

scattering due to Rayleigh and Raman signals and short-lived fluorescence background with consequent dramatic increase in signal-to-noise and detection sensitivity.

Time-resolved fluorometry[3] falls into one of two categories, depending on how the fluorescence emission response is measured: (1) pulse fluorometry, in which the sample is illuminated with an intense brief pulse of light and the intensity of the resulting fluorescence emission is measured as a function of time with a fast detector system, or (2) phase fluorometry, in which a continuous-wave laser illuminates the sample, and the fluorescence emission response is monitored for impulse and frequency response.[9]

Relationship of Concentration and Fluorescence Intensity

The relationship of concentration to intensity of fluorescence emission is derived from the Beer-Lambert law. By expansion through a Taylor series, rearrangement, logarithm base conversion, and basic assumptions about dilute solutions, the following equation is obtained:

$$F = \phi I_0 abc \tag{12}$$

where

F = relative intensity
ϕ = fluorescence efficiency (i.e., the ratio between quanta of light emitted and quanta of light absorbed)
I_0 = initial excitation intensity
a = molar absorptivity
b = volume element defined by geometry of the excitation and emission slits
c = the concentration in mol/L

Equation (12) indicates that fluorescence intensity is directly proportional to the concentration of the fluorophore and the excitation intensity. This relationship holds only for dilute solutions, where absorbance is less than 2% of the exciting radiation; the fluorescence intensity becomes nonlinear as the absorbance of the solution increases above 2% of the exciting radiation. This phenomenon is called the *inner filter effect*, and it is discussed in more detail in a later section. Other factors influencing the measurement of fluorescence intensity are the sensitivity of the detector and the degree of background light scatter seen by the detector.

Fluorescence intensity measurements are more sensitive than absorbance measurements. The magnitude of absorbance of a chromophore in solution is determined by its concentration and the path length of the cuvet. The magnitude of fluorescence intensity of a fluorophore is determined by its concentration, the path length, and the intensity of the light source. The sensitivity of fluorescence measurements can be 100 to 1000 times greater than the sensitivity of absorbance measurements through the use of more intense light sources, digital signal filtering techniques, and sensitive emission photometers. All of these are incorporated in conventional spectrofluorometric instrumentation, described later in this chapter.

Frequently, fluorescence measurements are expressed in relative intensity units. The word relative is used because the intensity measured is not an absolute quantity. It is a small part of the total fluorescence emission, and its magnitude is defined by the instrument slit width, detector sensitivity, monochromator efficiency, and excitation intensity. Because these are instrument-related variables, establishing an absolute intensity unit for a given concentration of a fluorophore that is valid from instrument to instrument is difficult, if not impossible.

Fluorescence Polarization

Light is composed of electrical and magnetic waves at right angles to each other. Light waves produced by standard excitation sources have their electrical vectors oriented randomly. Light waves, passed through certain crystalline materials (polarizers), have their electrical vectors oriented in a single plane and are said to be plane-polarized. Fluorophores absorb light most efficiently in the plane of their electronic energy levels. If their rotational relaxation (Brownian movement) is slower than their fluorescence decay time, as is the case for large fluorescent-labeled molecules, the emitted fluorescence light will be polarized. Because small molecules have rotational relaxation times that are much shorter than their fluorescence decay time, their emitted fluorescence light is depolarized. However, if the small fluorescent molecule is attached to a macromolecule or if it is placed in a viscous solution, the small molecule will emit polarized light. Fluorescence polarization, P, is defined by the following equation:

$$P = \frac{(I_v - I_h)}{(I_v + I_h)} \tag{13}$$

where

I_v = intensity of the emitted fluorescence light in the vertical plane

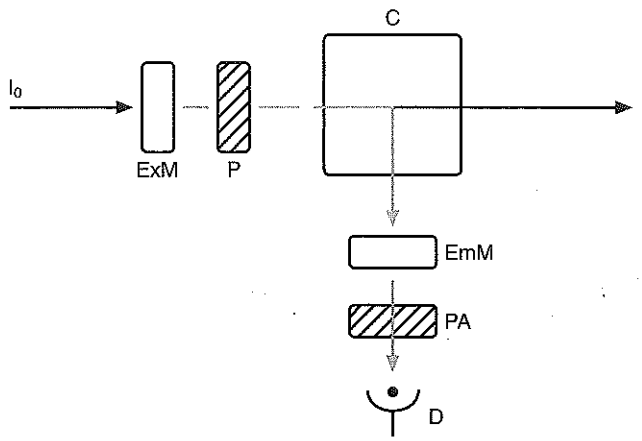

Figure 3-16 Schematic diagram of a fluorescence polarization analyzer. P is the polarizer to provide polarized excitation light. PA is the polarizer analyzer, which is rotated to provide the measurement of parallel and perpendicular polarized fluorescence-emission intensity. ExM is the excitation monochromator, EmM is the emission monochromator, D is the detector, and C is the reaction cell or cuvet.

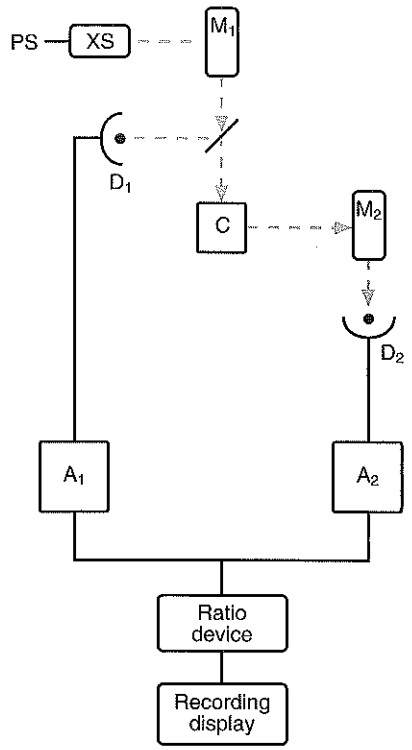

Figure 3-17 Block diagram of a typical spectrofluorometer: XS is the xenon source; PS is the power supply; M_1 is the excitation monochromator; C is the sample cell; M_2 is the emission monochromator. D_1 and D_2 are detectors; D_1 monitors the variation in excitation intensity and D_2 measures fluorescence emission intensity. A_1 and A_2 are excitation signal and emission signal amplifiers, respectively.

I_h = intensity of the emitted fluorescence light in the horizontal plane

As indicated, P is the difference between the two observed intensities divided by their sum. Fluorescence polarization is measured by placing a mechanically or electrically driven polarizer between the sample cuvet and the detector. A diagram of a fluorescence polarization measurement system is shown in Figure 3-16. In the normal instrumentation mode, the sample is excited with polarized light to obtain maximum sensitivity. The polarization analyzer is positioned first to measure the intensity of the emitted fluorescence light in the vertical plane (I_v), and then the polarization analyzer is rotated 90° to measure the emitted fluorescence light intensity in the horizontal plane (I_h). P is then calculated manually or automatically by use of equation (13).

Fluorescence polarization is used to quantitate analytes by use of the change in fluorescence depolarization following immunological reactions (see Chapter 9). Quantitation is accomplished by adding a known quantity of fluorescent-labeled analyte molecules to a reaction solution containing an antibody specific to the analyte. The labeled analyte binds to the antibody and causes a change in its rotational relaxation time, resulting in fluorescence polarization. The addition of a nonlabeled analyte, such as an unknown quantity of a therapeutic drug in a serum specimen, will result in a competition for binding to the antibody with the fluorescent-labeled analyte. This change in binding of the fluorophore-labeled analyte causes a change in fluorescence polarization that is inversely proportional to the amount of analyte contained in a given sample. Because the change in fluorescence polarization is a direct response to the reaction mixture, the bound fluorophore need not be separated from free fluorophore. Thus fluorescence polarization is applicable to homogeneous assays of low-molecular-weight analytes, such as therapeutic drugs.[11]

Instrumentation

Fluorometers and spectrofluorometers are used to measure fluorescence. Operationally, a fluorometer uses interference filters or glass filters to produce monochromatic light for sample excitation and for isolation of fluorescence emission, whereas a spectrofluorometer uses a grating or prism monochromator.

Components

Basic components of fluorometers and spectrofluorometers include (1) an excitation source, (2) an excitation monochromator, (3) a cuvet, (4) an emission monochromator, and (5) a detector. In Figure 3-17, these components are shown as they would be configured in a 90° optical system.

Excitation Source

The absorption spectra of most fluorescent compounds of interest are in the spectral region of 300 to 700 nm. The fluorescence emission intensity is proportional to the initial

excitation intensity and to concentration and size of the volume element being measured in the sample cell. Therefore, an intense lamp capable of emitting radiant energy over a large spectral region is desirable. Excitation sources used in fluorometers and spectrophotometers include xenon, quartz halogen, and mercury arc lamps and lasers. Some provide high-intensity spectra at one or more wavelengths, while others provide a continuum over the spectral range of interest.

Xenon Lamp. The xenon lamp is a popular excitation source as it provides a continuum of relatively high-intensity radiant energy over the spectral region of 250 to 800 nm. It is widely used for certain fluorescence applications because of its high energy output, stability of lamp flashes, and higher ultraviolet and visible spectral output. These flash lamps can be pulsed at rates up to 2500 pulses per second. Light output is typically in the 0.01- to 0.1-J interval, with a spectral distribution ranging from 250 to 800 nm. The life of flash lamps varies from 10^6 to 10^9 flashes, with the spectral stability being maintained throughout the life of the flash lamp. A limitation of xenon lamps for analytical use is arc wandering or flicker. However, the use of current-stabilized power supplies has minimized this problem and improved the performance of fluorescence instrumentation using xenon lamps.

Lasers. Laser sources (discussed earlier in the Spectrophotometry section) are widely used in fluorescence applications in which highly intense, well-focused, and essentially monochromatic light is required. Examples of these applications include time-resolved fluorometry, flow cytometry, pulsed laser confocal microscopy, laser-induced fluorometry, and light-scattering measurements for particle size and shape. Several different types of lasers are available as an excitation source for fluorescence measurements (see Table 3-3).

Excitation and Emission Monochromator

Monochromators used in fluorescence instrumentation include interference filters, colored glass filters, gratings, and prisms. Most modern analytical instruments using interference filters use the all-dielectric multicavity filter or a hybrid Fabry-Perot coupled-dielectric-layer filter (a filter with metal reflective layers). Either type of filter is combined with appropriate sharp cutoff glass filters to form a single filter package, which removes undesired transmission of higher orders and provides narrow bandwidth, higher peak wavelength transmission, and increased band slope. The increased slope of the spectral band makes the transition from peak transmission to nontransmission more abrupt, which is very important for the spectral separation of excitation and emission bands with a small Stokes shift.

Colored glass filters selectively absorb certain wavelengths of light. These filters have been used for both excitation and emission wavelength selection, but they are more susceptible to transmitting stray light and unwanted fluorescence.

Grating monochromators are devices that isolate regions of the spectrum. The spectral resolution of the light at the slit is a function of the slit width and the resolution of the grating. Spectrofluorometers generally use larger slit widths than absorbance spectrophotometers to obtain higher excitation intensities. An advantage of the grating monochromator is that it provides a selectivity of the excitation and emission wavelengths required when working with new fluorophores with absorbance and emission maxima for which specially fabricated interference filters may not exist. The rotation of the grating is digitally controlled when spectral scans of fluorescence excitation and emission are automated. In the conventional operation of a spectrofluorometer, either the excitation wavelength or the emission wavelength is held constant, and the other is scanned. With more automated instrumentation, both the excitation and emission monochromators are synchronized and scanned together at programmed rates. This provides a change in emission intensity as a function of change in excitation and emission wavelength and gives an additional dimension of specificity to fluorescence measurements. Due to their high degree of monochromaticity, lasers are being used as both the excitation light source and monochromator. When a laser is used as a combination excitation source and monochromator, a narrow-band interference filter is usually placed before the detector to eliminate additional orders of emission.

Cuvet

As with spectrophotometers, cuvets are used in fluorometers and spectrofluorometers to hold the liquid sample to be analyzed. However, with fluorescence instruments, the cuvets used are typically square or rectangular and are constructed from a material that allows the excitation and emitting light to pass (glass or plastic for visible light; quartz for ultraviolet light). However, some plastic cuvets contain ultraviolet absorbers that fluoresce, causing unwanted background signal and loss of sensitivity.

With fluorometers and spectrofluorometers, the placement of the cuvet and excitation beam relative to the photodetector is critical in establishing the optical geometry for fluorescence measurements. As fluorescence light is emitted in all directions from a molecule, several excitation/emission geometries are used to measure fluorescence (Figure 3-18). Most commercial spectrofluorometers and fluorometers use the right angle–detector approach, because it minimizes the background signal that limits analytical sensitivity. The end-on approach allows the adaptation of a fluorescence detector to existing 180° absorption instruments. Its sensitivity is limited by the quality of the excitation and/or emission interference filter pair, the excitation and/or emission spectral band overlap, and the inner filter effect. The front surface approach provides the greatest linearity over a broad range of concentration because it minimizes the inner filter effect.

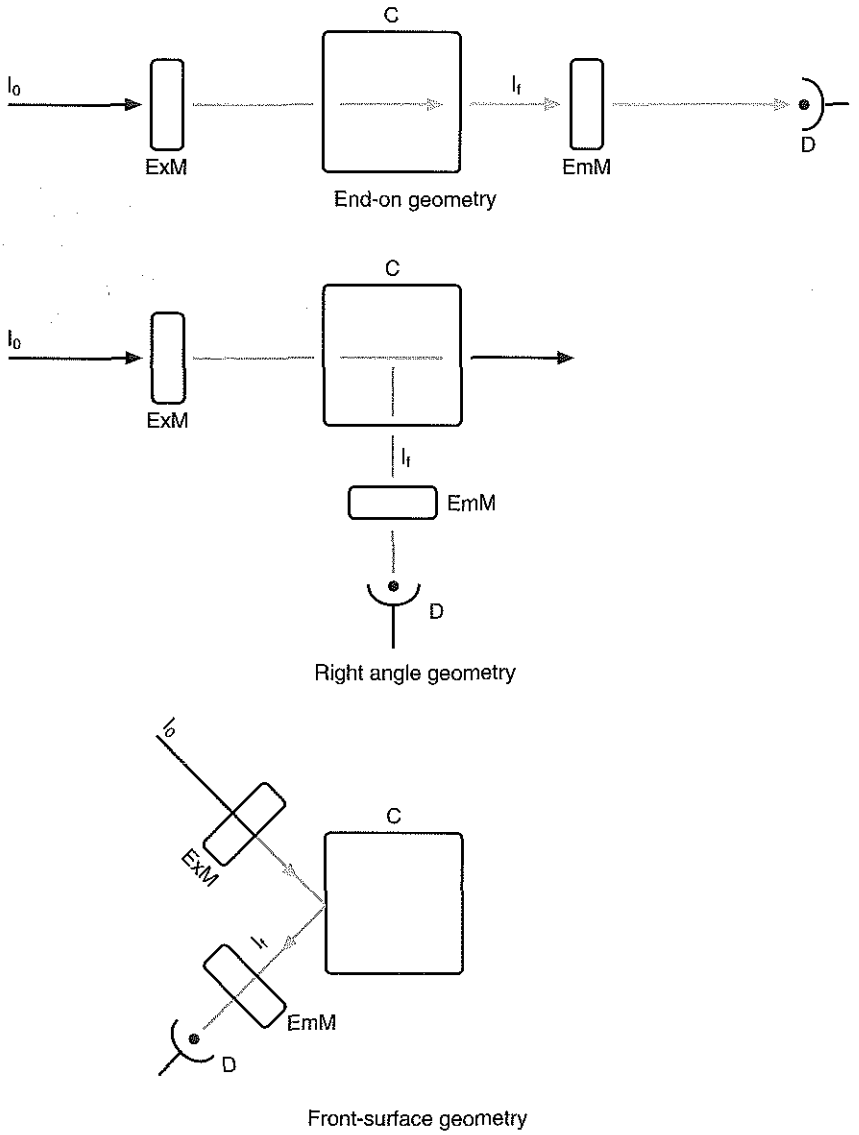

Figure 3-18 Fluorescence excitation/emission geometries: I_0 is the initial excitation energy; ExM is the excitation monochromator; C is the sample cuvet; I_f is the fluorescence intensity; EmM is the emission monochromator; and D is the detector.

The front surface approach shows similar sensitivity to the right angle detectors but is more susceptible to background light scatter. Front surface fluorometry has been widely applied to heterogeneous solid-phase fluorescence immunoassay systems.

To accommodate these different geometries, the sample cell is oriented at different angles in relation to the excitation source and the detector. The major concerns related to the geometry of the sample cell are light scattering, the inner filter effect, and the sample volume element seen by the detector. Figure 3-19 shows the sample cell and slit arrangement for a conventional fluorescence spectrophotometer with the excitation and emission slits oriented at a right angle. S_1 and S_2 designate the excitation and emission slits, respectively. The position of the emission slit and the width of the slit are important. If the emission slit is located near the front edge of the sample cell, as shown in Figure 3-19, *B*, the inner filter effect is minimized. If the emission slit width is increased, sensitivity will increase, but specificity may decrease.

Photodetectors

As with spectrophometric instruments, a number of devices are used as photodetectors in fluorometric instruments, including the photomultiplier tube (PMT) and charged-coupled detector (CCD). In addition, visual observation is used for some applications.

Visual Observation. Because the human eye is a very sensitive detector with a wide range of spectral recognition, qualitative fluorescent thin-layer methods in the clinical laboratory use short- and long-wavelength ultraviolet lamp source coupled with visual observation.

Photomultiplier Tube. For quantitative assays, the most commonly used detector in fluorometers and spectrofluo-

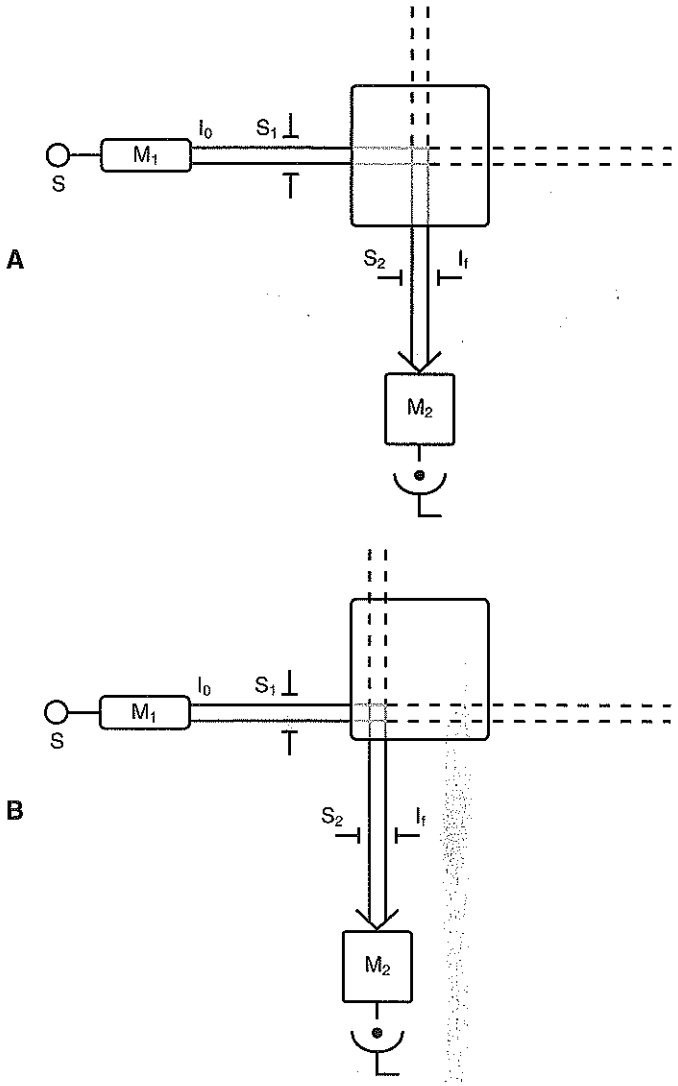

Figure 3-19 Two right angle fluorescence sample cuvet positions. **A** is the standard 90° configuration. **B** is the offset positioning of the cuvet to minimize the inner filter effect.

rometers is the PMT. The important features of the PMT for fluorescence measurements are a wide choice of spectral responses, rapid photon response time (i.e., nanosecond response time), and sensitivity. Sensitivity is due to the possible gain of 10^6 electrons at the anode of the photomultiplier tube for each incident photon hitting the photo cathode.

Depending on the light level (photon flux) striking the PMT cathode and the desired sensitivity, the measurement of electron flow at the PM tube anode is accomplished in different ways. At high light intensities, analog techniques for measurement of PMT current are used. The analog signal is then converted to a digital signal for computer use or for panel digital display. At low light levels, spikes or pulses generated at the cathode of the PMT are counted. The number of pulses that occur per unit of time is directly proportional to the intensity of emitted fluorescence light striking the PMT. This method is called *photon counting*. The use of photon counting increases the signal-to-noise ratio and the sensitivity of the measurement of fluorophores at very low concentrations.

Charge-Coupled Detector. CCDs are multichannel devices having dynamic range and a signal-to-noise ratio that are superior to those of photomultiplier tubes.[4,23] These solid-state devices are composed of a large number of photodetecting shift registers that are read horizontally and vertically. CCD were first used for astronomy applications and in ground-based optical telescopes in which sensitive low-light measurements are required. Because of their ability to detect very low levels of light, they have been used for molecular fluorescence measurement of very low concentrations of fluorescent molecules[23] and as a quantitative electronic imager for quantitative confocal microscopy.[12] A data-reading technique called binning has been developed that allows multielement devices to have functional elements linked together much like rectangular slit widths. A fluorometer has been built using a CCD and a 30-W mercury pen lamp as its light source. With this instrument, detection limits have been decreased by one order of magnitude.

Performance Verification

As with spectrophotometers, NIST provides a number of SRMs for use in the calibration or verification of the performance of fluorometers or fluorospectrophotometers. These include SRM 936a (quinine sulfate dihydrate) for calibrating such instruments and SRM 1932 (fluorescein) for establishing a reference scale for fluorescence measurements (see http://www.nist.gov).

Types of Fluorometers and Spectrofluorometers

Fluorometers and fluorescence spectrophotometers are available that offer a variety of features. These features include ratio referencing, microprocessor-controlled excitation and emission monochromators, pulsed xenon light sources, photon counting, rhodamine cell for corrected spectra, polarizers, flow cells, front-surface viewing adapters, multiple cell holders, and microprocessor-based data reduction systems.

In addition, to the basic spectrofluorometer discussed earlier (see Figure 3-17), other types of fluorometric instruments include a ratio-referencing spectrofluorometer, time-resolved fluorometer, flow cytometer, and hematofluorometer.

Ratio-Referencing Spectrofluorometer

A typical ratio-referencing spectrofluorometer is illustrated in Figure 3-20. Basically, this is a simple right angle instrument that uses two monochromators (M1 and M2), two photomultiplier tube detectors (D1 and D2, the reference and sample PMTs), and a xenon lamp source. The light from the exciter monochromator (M1) is split, and a small portion (10%) is directed to the reference PMT (D1) for ratio refer-

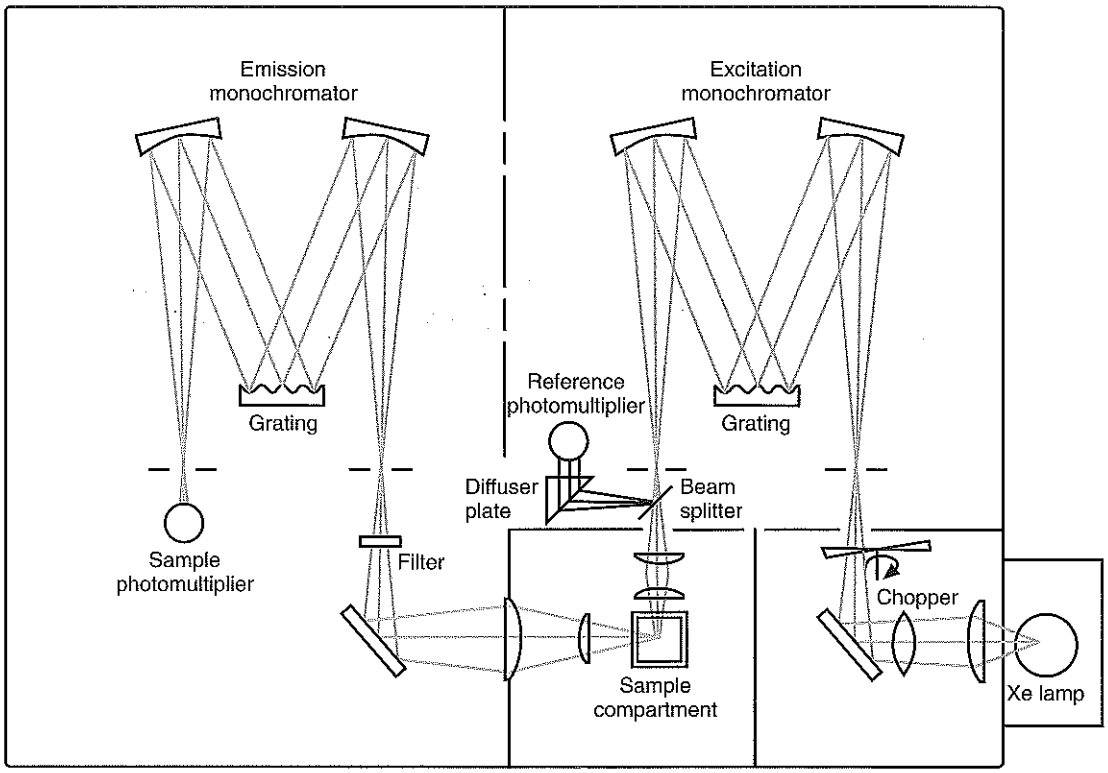

Figure 3-20 Diagram of a typical ratio-referencing spectrofluorometer.

encing purposes. The remaining excitation light is focused into the sample cuvet (C). Emission optics are positioned at a right angle to the excitation optics. An emission monochromator (M2) is used to select or scan the desired portion of the emission spectra, which is directed to the sample PMT (D2) for measurement of the emission intensity. The output signals from the reference and the sample PMTs are amplified (A1 and A2), and a ratio of the sample to the reference signal is provided by a digital display or a chart recorder. The operational mode of a ratio fluorometer is similar to that of the spectrofluorometer; however, only discrete excitation and emission wavelengths are available, and the use of this type of instrument is precluded from scanning fluorophores to obtain emission and excitation spectra. The ratio filter fluorometer is most useful for obtaining concentration measurements at defined excitation and emission wavelengths.

The ratio-referencing spectrofluorometer is operated at either fixed excitation and emission wavelength settings for concentration measurements or used to measure the excitation or emission spectrum of a given compound. The measurement of concentration of unknowns is accomplished in a similar manner as with a single-beam fluorometer. A blank and a calibrating solution are first measured, and then the unknown samples are measured. The ratio-referencing spectrofluorometer in Figure 3-20 provides two advantages over single-beam spectrofluorometers. First, it eliminates short- and long-term xenon lamp energy fluctuations (i.e., arc flicker and lamp decay) and thus minimizes the need for frequent calibration of the instrument during analysis. Second, it provides "essentially" corrected excitation spectra by compensating for wavelength-dependent energy fluctuations.

Time-Resolved Fluorometers

The time-resolved fluorometer was introduced in the mid-1970s when Weider developed a pulsed nitrogen laser fluorometer in conjunction with a lanthanide-based immunoassay system to measure the fluorescence decay of lanthanide chelates as a means of eliminating background interferences from light scatter and short decay time fluorescence compounds.[26] The time-resolved fluorometer[3,18] is similar to the ratio-referencing fluorometer with the exception that the light source is pulsed and that the detector monitors, in a fast photon-counting mode, the exponential decay of the fluorescence signal after the excitation. Time-resolved fluorometry requires the use of long-lived fluorophores, such as the lanthanide (rare earth) metal ions europium (Eu^{3+}) and samarium (Sm^{3+}). Whereas most fluorescence compounds have decay times of 5 to 100 ns, europium chelates decay in 0.6 to 100 s. Thus time-resolved fluorescence assays take advantage of the difference in the lifetimes of fluorophore and the background fluorescence by measuring the decaying fluorescence signal. This eliminates background interferences and at the same time averages the signal to improve the precision of measurement. Detection limits of approximately 10^{-13} mol/L can be achieved with

time-resolved fluorometry; this is an improvement of about four orders of magnitude compared with conventional fluorometric measurements. For example, Eu^{3+}-labeled nanoparticles in combination with time-resolved fluorometry have been used to develop a highly sensitive immunoassay for free and total prostate specific antigen having a functional sensitivity of 0.5 ng/L.[8,19,20]

Flow Cytometer

Cytometry refers to the measurement of physical and/or chemical characteristics of cells, or, by extension, of other biological particles. Flow cytometry is a process in which such measurements are made while the cells or particles pass, preferably in single file, through the measuring apparatus in a fluid stream. Flow sorting extends flow cytometry by using electrical or mechanical means to divert and collect cells with one or more measured characteristics falling within a range or ranges of values set by the user.[14,16]

Operationally, flow cytometry combines laser-induced fluorometry and particle light scattering analysis that allows different populations of molecules, cells, or particles to be differentiated by size and shape using low-light and right angle light scattering. The use of a laser is ideally suited for low-angle light scattering. These cells, molecules, or particles are labeled with different specific fluorescent labels, such as β-phycoerythrin, fluorescein isothiocyanate, rhodamine-6G, and dye-labeled antibodies. As they flow through the flow cell, simultaneous fluorescence and light scattering measurements are automatically performed by the flow cytometer. Most flow cytometers incorporate two or more fluorescence emission detection systems so that multiple fluorescent labels can be used. In this manner, molecules, cells, or particles can be classified by size, shape, and type according to their light-scattering and fluorescent properties. A schematic diagram of a flow cytometer is shown in Figure 3-21. An optical stop is placed in the 180° beam after the flow capillary to block the main laser beam and permit low-angle forward light scattering measurements. The 90° emission signal is split and directed to two PMTs to determine right angle light scattering and detect at least two separate fluorescence emission signals. Two narrow-bandpass interference filters (530 nm and 596 nm) are placed in front of the two 90° fluorescence emission PMTs. A computer with substantial resident software is employed to reduce the acquired data to appropriate histograms for final result reporting. Cell-sorting electrodes are shown in the schematic drawing. Most commercial flow cytometers use a single argon ion laser (488 nm), which excites fluorescein isothiocyanate and phycoerythrin. When excited, fluorescein isothiocyanate–labeled cells emit green light (E_{max} = 530 nm), and phycoerythrin-labeled cells emit orange light (E_{max} = 596 nm).

Flow cytometers are able to measure multiple parameters, including cell size (forward scatter), granularity (90° scatter), DNA content, RNA content, DNA (A + T)/(G + C) nucleotide ratios, chromatin structure, antigens, total protein content, cell receptors, membrane potential, and calcium ion concentration as a function of pH. These parameters are used in hematology, immunology (e.g., in T-cell subsets, tissue typing, lymphocyte stimulation, and antigen-antibody reactions), oncology (e.g., in diagnosis, prognosis, and treatment monitoring), microbiology (e.g., in bacterial identification and antibiotic sensitivity), virology, genetics

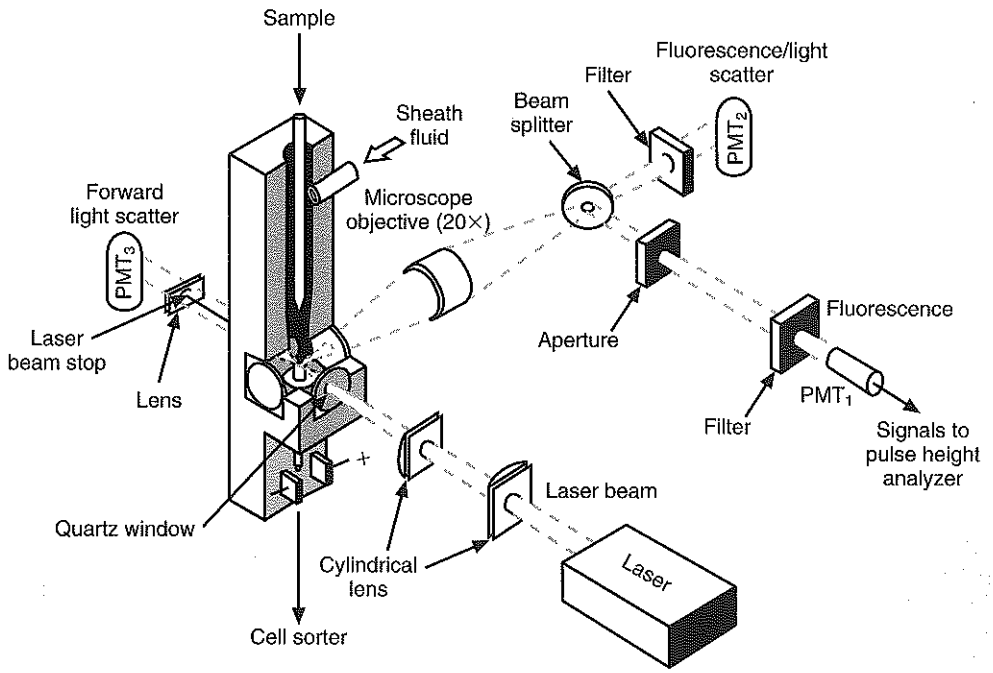

Figure 3-21 Schematic diagram of a flow cytometer.

(e.g., in karyotyping and carrier state detection), parasitology, reproduction and fertility studies, and possibly may have application in cervical cytology. Flow cytometry also has potential applications for the development of sensitive laser-induced fluoroimmunoassays. Phycoerythrin is a large phycobiliprotein molecule (MW = 250,000) with the fluorescence emission equivalent of 25 rhodamine-6G molecules, a quantum yield of 0.98, a broad emission spectrum of 530 to 630 nm, and low photodecomposition. It is an excellent label for cells and possibly for use in new fluoroimmunoassays.

Of particular note has been the development and use of particle-based flow cytometric assays. With this technology, a flow cytometer is combined with microspheres that are used as the solid support for conventional immunoassay, affinity assay, or DNA hybridization assay.[25] The resultant system is very flexible and has led to the development of multiplexed assays that simultaneously measure many different analytes in a small sample volume.

Hematofluorometer

The *hematofluorometer* is a single-channel front surface photofluorometer dedicated to the analysis of zinc protoporphyrin in whole blood (see Chapter 32). A typical hematofluorometer uses a quartz tungsten lamp, a narrow bandpass excitation filter (420 nm), front surface optics, a narrow bandpass filter (594 nm), and a PM tube. A drop of whole blood is placed on a small rectangular glass slide that serves as a cuvet.

Limitations of Fluorescence Measurements

Factors that influence fluorescence measurements include concentration effects (e.g., inner filter effect and concentration quenching), background effects (due to Rayleigh and Raman scattering), solvent effects (e.g., interfering nonspecific fluorescence and quenching from the solvent), sample effects (e.g., light scattering, interfering fluorescence, and sample adsorption), temperature effects, and photodecomposition (bleaching) of the sample.

Inner Filter Effect

The linear relationship between concentration and fluorescence emission (equation [12]) is valid when solutions are used that absorb less than 2% of the exciting light. As the absorbance of the solution increases above this amount, the relationship becomes nonlinear, a phenomenon known as the "inner filter effect." It is caused by a loss of excitation intensity across the cuvet path length as the excitation light is absorbed by the fluorophore. Thus as the fluorophore becomes more concentrated, the absorbance of the excitation intensity increases, and the loss of the excitation light as it travels through the cuvet increases. This effect is most often encountered with a right angle fluorescence instrument, in which the emission slits are set to monitor the center of the sample cell where the absorbance of excitation light is greater than at the front surface of the cuvet. Therefore it is less problematical if a front surface fluorescence instrument is used. However, most fluorescence measurements are made on very dilute solutions and the inner filter effect is therefore not a problem.

Concentration Quenching

Another related phenomenon that results in a lower quantum yield than expected is called *concentration quenching*. This can occur when a macromolecule, such as an antibody, is heavily labeled with a fluorophore, such as fluorescein isothiocyanate. When this compound is excited, the fluorescence labels are in such close proximity that radiationless energy transfer occurs. Thus, the resulting fluorescence is much lower than expected for the concentration of the label. This is a common problem in flow cytometry and laser-induced fluorescence when attempting to enhance detection sensitivity by increasing the density of the fluorescing label.

Light Scattering

Light scattering, both Rayleigh and Raman, limit the use of fluorescence measurements. Rayleigh scattering occurs with no change in wavelength. For fluorophores with small Stokes shifts, the excitation and emission spectra overlap and are particularly susceptible to loss of sensitivity because of background light scatter. Rayleigh-type light scatter is controlled by the use of well-defined emission and excitation interference filters or by appropriate monochromator settings and by the use of polarizers.

Raman scattering occurs with a lengthening of wavelength. This type of light scattering is independent of excitation wavelength and is a property of the solvent. Because Raman light scattering appears at longer wavelengths than the exciting radiation, it is a difficult interference to eliminate when working at very low fluorophore concentrations. As an example, the wavelength shift in water is ~50 nm at an excitation wavelength of 365 nm and ~75 nm at an excitation wavelength of 436 nm. The shift would represent a problem if the excitation maximum of a fluorophore was 365 nm and the emission maximum was 415 nm. Raman light scattering is controlled by setting the excitation and emission wavelengths far enough apart to prevent the Raman scatter. Also, it is controlled by narrowing the slit width on the excitation monochromator. However, both options tend to decrease sensitivity.

Cuvet Material and Solvent Effects

Certain quartz glass and plastic materials that contain ultraviolet absorbers will fluoresce. Some solvents, such as ethanol, are also known to cause appreciable fluorescence. It is therefore important when developing a fluorescence assay to assess the background fluorescence of all components of the reaction mixture. Fluorescence grade solvents and cuvets with minimum fluorescence emission, which minimize these types of fluorescence background problems, are commercially available.

Quenching by the solvent can be a problem and should be investigated when setting up a new fluorometric method. Quenching is related to the interaction of the fluorophore with the solvent or with a solute dissolved in the solvent. Such interaction results in a loss of fluorescence owing to energy transfer or other mechanisms, but there is no effect on the absorbance spectrum of the fluorophore. An example of quenching is the loss of fluorescence when halides are added to quinine in dilute sulfuric acid. Quenching can be a useful tool for studying molecular structure, because fluorescence emission is sensitive to and specific for changes in atomic and molecular structure.

Sample Matrix Effects

A serum or urine sample contains many compounds that fluoresce. Thus the sample matrix is a potential source of unwanted background fluorescence and must be examined when new methods are developed. The most serious contributors to unwanted fluorescence are proteins and bilirubin. However, because protein excitation maxima are in the spectral region of 260 to 290 nm, their contribution to overall background fluorescence is minor when excitation occurs above 300 nm.

The light scattering of proteins and other macromolecules in the sample matrix has been known to cause unwanted background fluorescence. Lipemic samples, for example, are noted for their intense light scattering, and the relative contribution of lipids to the background signal of a fluorescence measurement should be investigated when setting up a new method.

In addition to background interferences, dilute solutions of some fluorophores in the concentration range of 10^{-9} mol/L and below will absorb to the walls of glass cuvets and other reaction vessels. Also, dilute solutions of fluorophores, when excited over long periods of time, are susceptible to photodecomposition by intense excitation light. Operationally, these problems are avoided by selecting proper reaction vessels, adding wetting agents, and minimizing the length of time a sample is exposed to the excitation light.

Temperature Effects

The fluorescence quantum efficiency of many compounds is sensitive to temperature fluctuations. Therefore, the temperature of the reaction must be regulated to within ±0.1°C. In general, fluorescence intensity decreases with increasing temperature by approximately 1% to 5% per degree Celsius. Furthermore, collisional quenching decreases with increasing viscosity, thus reducing quenching of fluorescence. Operationally, fluorescence intensity is therefore enhanced by either increasing reaction viscosity or lowering solvent temperature. Temperature effects are minimized by controlling reaction temperature and warming samples or reagents, or both, if they have been refrigerated.

Photodecomposition

In conventional fluorometry, excitation of weakly fluorescing or dilute solutions with intense light sources will cause photochemical decomposition of the analyte (photobleaching).

The following steps help to minimize photodecomposition effects:

1. Always use the longest feasible wavelength for excitation that does not introduce light-scattering effects.
2. Decrease the duration of excitation of the sample by measuring the fluorescence intensity immediately after excitation.
3. Protect unstable solutions from ambient light by storing them in dark bottles.
4. Remove dissolved oxygen from the solution.

In addition, highly intense laser light sources with an energy output greater than 5 to 10 mW that are used for flow cytometry, fluorescence microscopy, and laser-induced fluorescence measurements will rapidly photodecompose some fluorescence analytes. This decomposition introduces nonlinear response curves and loss of the majority of the sample fluorescence. Fluorescence-based assays for analytes at ultralow concentrations require optimization of laser intensity and the use of a sensitive detector.

PHOSPHORESCENCE

Phosphorescence is the luminescence produced by certain substances after absorbing radiant energy or other types of energy.[24] Phosphorescence is distinguished from fluorescence in that it continues even after the radiation causing it has ceased. The decay time of emission of phosphorescence light is longer ($10^{-4} - 10^{2}$ s) than the decay time of fluorescence emission. Decay times are expressed in a time range of several orders of magnitude and vary with the molecule and its solution environment. Phosphorescence shows a larger shift in emitted light wavelength than does fluorescence.

CHEMILUMINESCENCE, BIOLUMINESCENCE, AND ELECTROCHEMILUMINESCENCE

Chemiluminescence, bioluminescence, and *electrochemiluminescence* are types of luminescence in which the excitation event is caused by a chemical, biochemical, or electrochemical reaction and not by photoillumination.

Basic Concepts

The physical event of the light emission in chemiluminescence, bioluminescence, and electrochemiluminescence is similar to fluorescence in that it occurs from an excited singlet state, and the light is emitted when the electron returns to the ground state.

Chemiluminescence and Bioluminescence

Chemiluminescence is the emission of light when an electron returns from an excited or higher energy level to a lower energy level. The excitation event is caused by a chemical reaction and involves the oxidation of an organic compound, such as luminol, isoluminol, acridinium esters, or luciferin, by an oxidant (e.g., hydrogen peroxide, hypochlorite, or oxygen); light is emitted from the excited product formed in the oxidation reaction. These reactions occur in the presence of catalysts, such as enzymes (e.g., alkaline phosphatase, horseradish peroxidase, and microperoxidase), metal ions or metal complexes (e.g., Cu^{2+} and Fe^{3+} phthalocyanine complex), and hemin.[2,6,7,13,27]

Bioluminescence is a special form of chemiluminescence found in biological systems. In bioluminescence, an enzyme or a photoprotein increases the efficiency of the luminescence reaction. Luciferase and aequorin are two examples of these biological catalysts. The quantum yield (e.g., total photons emitted per total molecules reacting) is approximately 0.1% to 10% for chemiluminescence and 10% to 30% for bioluminescence.

Chemiluminescence assays are ultrasensitive (attomole to zeptomole detection limits) and have wide dynamic ranges. They are now widely used in automated immunoassay and DNA probe assay systems, (e.g., acridinium ester and acridinium sulfonamide labels and 1,2-dioxetane substrates for alkaline phosphatase labels and the enhanced-luminol reaction for horseradish peroxidase labels [see Chapter 9]).

Electrochemiluminescence

Electrochemiluminescence differs from chemiluminescence in that the reactive species that produce the chemiluminescent reaction are electrochemically generated from stable precursors at the surface of an electrode.[1] A ruthenium (Ru^{2+}), tris(bipyridyl) chelate is the most commonly used electrochemiluminescence label and electrochemiluminescence is generated at an electrode via an oxidation-reduction–type reaction with tripropylamine. This chelate is very stable and relatively small and can be used to label haptens or large molecules (e.g., proteins or oligonucleotides). The electrochemiluminescence process has been used in both immunoassays and nucleic acid assays. The advantages of this process are improved reagent stability, simple reagent preparation, and enhanced sensitivity. With its use, detection limits of 200 fmol/L and a dynamic range extending over six orders of magnitude can be obtained.

Instrumentation

Luminometers are instruments used to measure chemiluminescence and electrochemiluminescence.[2,27] The basic components are (1) the sample cell housed in a light-tight chamber, (2) the injection system to add reagents to the sample cell, and (3) the detector. The detector is usually a photomultiplier tube. However, a CCD, x-ray film, or photographic film has been used to image chemiluminescence reactions on a membrane or in the wells of a microplate. For electrochemiluminescence, the reaction vessel incorporates an electrode at which the electrochemiluminescence is generated.

Limitations of Chemiluminescence and Electrochemiluminescence Measurements

Light leaks, light piping, and high background luminescence from assay reagents and reaction vessels (e.g., plastic tubes exposed to light) are common factors that degrade analytical performance. The extreme sensitivity of chemiluminescence assays requires stringent controls on the purity of reagents and the solvents (e.g., water) used to prepare reagent solutions. Efficient capture of the light emission from reactions that produce a flash of light requires an efficient injector that provides adequate mixing when the triggering reagent is added to the reaction vessel. Chemiluminescent and electrochemiluminescent assays have a wide linear range, usually several orders of magnitude, but very high intensity light emission can lead to pulse pile-up in photomultiplier tubes and this leads to a serious underestimate of the true light emission intensity.

NEPHELOMETRY AND TURBIDIMETRY

Light scattering is a physical phenomenon resulting from the interaction of light with particles in solution. Nephelometry and turbidimetry are analytical techniques used to measure scattered light. Light-scattering measurements have been applied to immunoassays of specific proteins and haptens. Specific applications are described in Chapters 9, 20, and 26.

Basic Concepts

Light scattering occurs when radiant energy passing through a solution encounters a molecule in an elastic collision, which results in the light being scattered in all directions. Unlike fluorescence emission, the scattered light is of the same frequency as the incident light.

Factors that influence light scattering include the effect of particle size, wavelength dependence, distance of observation, effect of polarization of incident light, the concentration of the particles, and the molecular weight of the particles.

Particle Size

The Rayleigh scattering equation (see next section) applies to the scattering of light from small particles with much smaller dimensions than the wavelength of incident light (e.g., particle size $<\lambda/10$). When the dimensions of the particles are much smaller than the wavelength of the incident light, each particle is subjected to the same electric field strength at the same time. The reradiated or scattered light waves from the small particle are in phase and reinforce each other. As the particles become larger than the incident light wave, the radiated light waves are no longer all in phase.

Reinforcement of radiation occurs in some directions, and destructive interference occurs in others. The scattering patterns from these large particles are characteristic of the size and shape of the particle.

Wavelength Dependence of Light Scattering

In 1871 Lord Rayleigh derived the following equation that demonstrates the relationship of the intensity (I_s) of scattered light to the intensity (I_0) of the incident light:

$$\frac{I_s}{I_0} = \frac{16\pi^2 a \sin^2\theta}{\lambda^4 r^2} \qquad (14)$$

where

I_s = intensity of scattered light
I_0 = intensity of the excitation light
a = polarizability of the small particle
θ = angle of observation
λ = wavelength of the incident light
r = distance from light scattering to the detector

As indicated, the intensity of light scattering increases by the fourth power of the wavelength as the wavelength of the incident light is decreased. Another useful observation from equation (14) is the fact that the light intensity decreases by the square of the distance r from the light-scattering particles to the detector. Thus, the detector should be located close to the analytical cell either by the juxtaposition of the cell to the detector or by the use of good collection optics.

Concentration and Molecular Weight Factors in Light Scattering

The direct relationship of light scattering to the concentration of the particles and to the molecular weight of the particles is derived from equation (14) showing that:

$$\frac{I_S}{I_0} = \frac{4\pi^2 (dn/dc)^2 Mc \sin^2\theta}{N_a \lambda^4 r^2} \qquad (15)$$

where

I_S = intensity of scattered light from small particles excited by polarized light
I_0 = incident intensity
dn/dc = change in refractive index of the solvent with respect to change in solute concentration
M = molecular weight (g/mol)
c = concentration (g/mL) of the particles
θ = angle of observation
N_a = Avogadro's number
λ = wavelength of the incident light
r = distance from light scattering to the detector

The important observation to be made from equation (15) is the direct relationship of light scattering to the concentration of the particles and to the molecular weight of the particles.[24]

The Effect of Polarized Light on Light Scattering

Equations (14) and (15) are different forms of the Rayleigh expression for light scattering from small particles if excited by polarized light. Figure 3-22, *A* shows the effect of polarized and nonpolarized light on light-scattering intensity from small particles as a function of scattering angle. Curve 2 shows a spherically symmetrical intensity diagram as predicted by equation (14). Curve 3 is the resultant intensity diagram when curves 1 and 2 are summed and is the scattering angular intensity diagram obtained when light scatters from small particles excited with nonpolarized light. Curves 1 and 2 represent intensity diagrams from vertically and horizontally polarized light components that are considered to be comprising nonpolarized light. The Rayleigh light-scattering expression for small particles excited by nonpolarized light is given by equation (16):

$$\frac{I_S}{I_0} = \frac{2\pi^2 (dn/dc)^2 Mc(1 + \cos\theta)}{N_a \lambda^4 r^2} \qquad (16)$$

There are two important observations to be made from equation (16) and Figure 3-22, *A*. First, the total light scattered by small particles is less when excited by polarized light than by nonpolarized light, and a reduction of background signal from light scattering in fluorescence measurements is achieved if an appropriately oriented polarizer is used in front of the emission detector. Second, the light-scattering

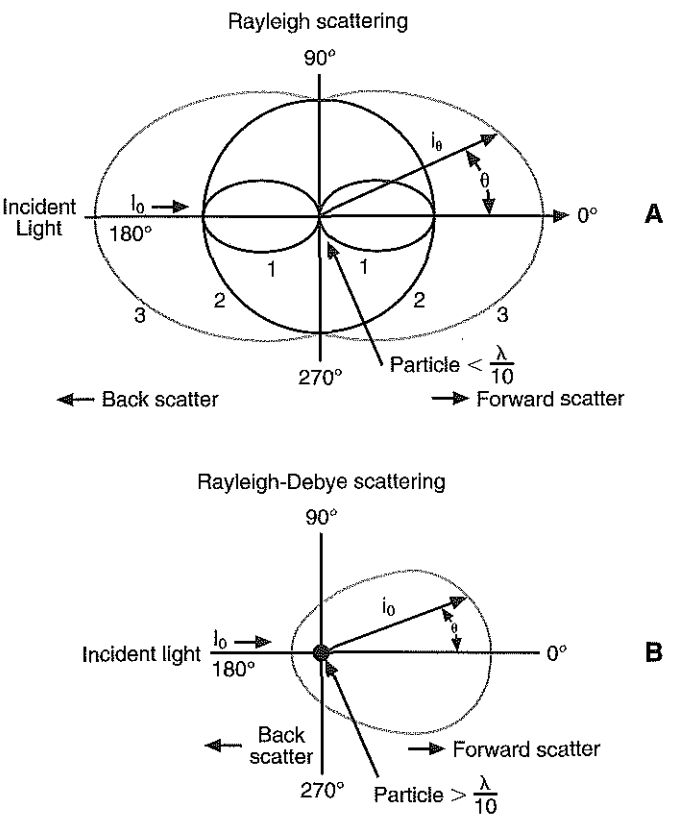

Figure 3-22 The angular dependence of light-scattering intensity with nonpolarized and polarized incident light for small particles **(A)** and the angular dependence of light scattering with nonpolarized light for larger particles **(B)**.

intensity from small particles excited by nonpolarized light shows a symmetrical angular dependence of light scattering about the 90° axis (refer to Figure 3-22, *A*, curve 3).

The Angular Dependence of Light Scattering

The angular dependence of light scattering from small particles (i.e., less than λ/10), as indicated in the previous section, is represented by Figure 3-22, *A*. Examination of Figure 3-22, *A* (curve 3) shows that the light scatter intensity for forward scatter and back scatter (I_0 at 0° and 180°) from small particles excited by nonpolarized light is equal. However, light scatter intensity at 90° is much less. As the size of particles becomes larger (e.g., >λ/10), the angular dependence of light scatter takes on the dissymmetrical relationship shown in Figure 3-22, *B*. In this situation, the light-scattering intensities at forward and back angles are not equal; the forward scatter intensity is much larger. Also, the light-scattering intensity at 90° is much less than the intensity at the forward (0°) angle. As particles become even larger, this dissymmetry increases even further. This dissymmetry and the change of angular dependence of light scattering with change in the size of particles is very useful for characterization and differentiation of various classes of macromolecules and cells. As was previously mentioned, this property of light scattering is being used in the design of flow cytometers. These instruments measure near forward light scattering and right angle light scattering from cellular particles flowing through an optical cell and excited by a high-intensity laser. The ratio of the near forward light scattering intensity to the right angle light intensity is used in these instruments to distinguish different cell sizes.

Light Scattering and Plasma Proteins

The expression for light scattering given in equation (14) holds true in dilute solution for small particles if the largest dimension is less than one tenth of the wavelength of the incident light. Thus the upper limit on size of particles exhibiting Rayleigh scattering is about 40 nm when using visible light at 400 nm. Many of the plasma proteins—such as immunoglobulins, β-lipoproteins, and albumin—are below this limit. For larger particles (~40 to 400 nm), the angular dependence of the scattered light loses the symmetry around the 90° axis as seen in Figure 3-22, *A* and *B* and shows an increase in forward scattering. Some plasma proteins of the immunoglobulin M class, chylomicrons, and aggregating immunoglobulin/antigen complexes fall into this size category. The scattering from particles in this size range is known as Rayleigh-Debye scattering, and the equation for this type of scattering becomes more complex. Particles, such as red blood cells and bacteria, are larger yet (i.e., 7000 to 40,000 nm). These particles show a complex angular dependence of light scattering, and this type of scattering from very large particles is called Mie scattering. These large particles produce a predominance of scattered light in a narrow angular region in the forward direction.

Measurement of Scattered Light

Turbidimetry and nephelometry are methods used to measure scattered light. Their measurement has proven useful for the quantitation of serum proteins (see Chapters 9 and 20).

Turbidimetry

Turbidity decreases the intensity of the incident beam of light as it passes through a solution of particles. The measurement of this decrease in intensity is called turbidimetry. Analogous to absorption spectroscopy, the turbidity is defined as:

$$I = I_0 e^{-bt} \tag{17}$$

or

$$t = \frac{1}{b} \ln \frac{I_0}{I} \tag{18}$$

where

t = turbidity
b = path length of the incident light through the solution of light-scattering particles
I = intensity of transmitted light
I_0 = intensity of incident light

Turbidity is measured at 180° from the incident beam, or more simply, in the same manner as absorbance measurements are made in a spectrophotometer. Turbidity can be measured on most spectrophotometers and automated clinical chemistry analyzers. The stability and resolution of modern microprocessor-driven spectrophotometers and photometers have greatly improved the ability to measure turbidity with accuracy and precision.

Nephelometry

Nephelometry is defined as the detection of light energy scattered or reflected toward a detector that is not in the direct path of the transmitted light.[10] Common nephelometers measure scattered light at right angles to the incident light. The ideal nephelometric instrument would be free of stray light and neither light scatter nor any other signal would be seen by the detector when the solution in front of the detector is free from particles. However, because of stray light-generating components in the optical system and in the sample cuvet or sample itself, a truly dark field situation is difficult to obtain when making nephelometric measurements. Some nephelometers are designed to measure scattered light at an angle other than 90° to take advantage of the increased forward-scatter intensity caused by light scattering from larger particles (e.g., immune complexes).

Selection of Method

The choice between turbidimetry and nephelometry depends on the application and the available instrumentation. Nephelometry, however, still offers some advantage in sensitivity when measuring low-level antigen-antibody reactions.[10]

Instrumentation

Turbidimeters and nephelometers are used to measure the intensity of light scattering.

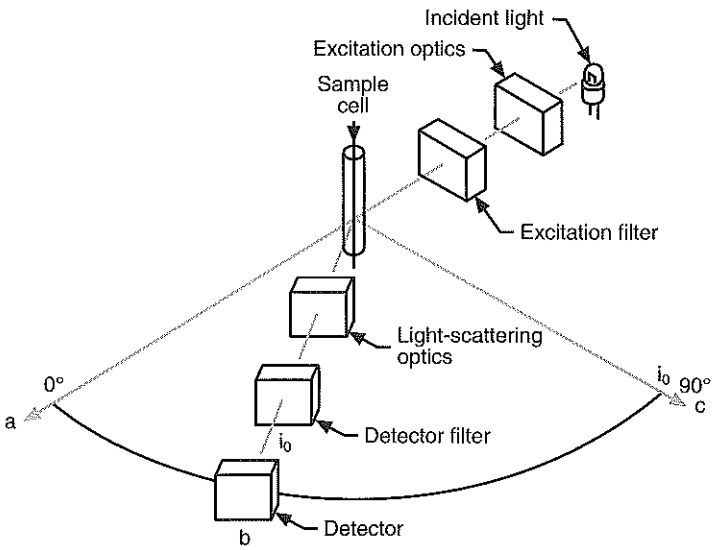
Turbidimeter

Turbidimetric measurements are easily performed on photometers or spectrophotometers and require little optimization. The principal concern of turbidimetric measurements is signal-to-noise ratio. Photometric systems with electro-optical noise in the range of ±0.0002 absorbance unit or less are useful for turbidity measurements.

Nephelometer

Although light scattering can be measured with standard analytical fluorometers or photometers, the angular dependence of light-scattering intensity has resulted in the design of special nephelometers. These devices place the PMT detector at appropriate angles to the excitation light beam. The design principle of a nephelometer is similar to the design principle applied in fluorescence measurements. The major operational difference between the fluorometer and the nephelometer is that the excitation and detection wavelengths will be set to the same value. The principal concerns of light scatter instrumentation are excitation intensity, wavelength, distance of the detector from the sample cuvet, and minimization of external stray light. As shown in Figure 3-23, the basic components of a nephelometer include (1) a light source, (2) collimating optics, (3) a sample cell, and (4) collection optics, which include light-scattering optics, detector optical filter, and a detector. The schematic diagram also shows the different angles from the incident light beam where the detector, filter, and optics are placed to measure light scattering. Figure 3-23, *A* is the straight-through arrangement for turbidimetry, whereas Figure 3-23, *B* and *C* are arrangements frequently found in nephelometers. The detector arrangement shown in Figure 3-23, *B* is for measurement of forward scatter at 30°, the optical arrangement used in some commercial nephelometers.

Operationally, the optical components used in turbidimeters and nephelometers are similar to those used in fluorometers or photometers. For example, the light sources commonly used are quartz halogen lamps, xenon lamps, and lasers. He-Ne lasers, which operate at 633 nm, have typically been used for light-scattering applications, such as nephelometric immunoassays and particle size and shape determinations. The laser beam is used specifically in some nephelometers because of its high intensity; in addition, the coherent nature of laser light makes it ideally suited for nephelometric applications.



In addition, ratio-referencing fluorometers are well suited for nephelometric measurements.

Limitations of Light-Scattering Measurements

Antigen excess and matrix effects are limitations encountered in the use of turbidimeters and nephelometers in measurement of analytes of clinical interest.

Antigen Excess

Antigen-antibody reactions are complex and appear to result in a mixture of aggregate sizes. As the turbidity increases during addition of antigen to antibodies, the signal increases to a maximum value and then decreases. The point at which the decrease begins marks the beginning of the phase of antigen excess; this phenomenon is explained in Chapter 9.

(a) = 0° Turbidimeter

(b) = 30° Forward-scatter nephelometry

(c) = 90° Nephelometer

Figure 3-23 Schematic diagram of light-scattering instrumentation showing **A,** the optics position for a turbidimeter; **B,** the optics position for a forward-scattering nephelometer; and **C,** the optics position for a right angle nephelometer.

Consequently, light-scattering methods for quantitation of antigen-antibody reactions must provide a method for detecting antigen excess. The kinetics of immune complex formation measured either by nephelometry or turbidimetry are sufficiently different in the three phases—antibody excess, equivalence, and antigen excess—that computer algorithms have been developed to flag antigen excess automatically.[10,21]

Matrix Effects

Particles, solvent, and all serum macromolecules scatter light. Lipoproteins and chylomicrons in lipemic serum provide the highest background turbidity or nephelometric intensity. With appropriate dilutions, the relative intensity of light scattering from a lipemic sample is less than that of the antiserum blank. However, as the concentration of the antigen in serum decreases and correspondingly less dilute samples are used, the background interference from lipemic samples becomes greater. An effective method for minimizing this background interference is the use of rate measurements, where the initial sample blank is eliminated.

Large particles, such as suspended dust, also cause significant background interference. This background interference is controlled by filtering all buffers and diluted antisera before analysis is attempted.

CHAPTER 4

Electrochemistry and Chemical Sensors*

Paul D'Orazio, Ph.D., and Mark E. Meyerhoff, Ph.D.

Electrochemical and optical sensors (and associated biosensors) are firmly established in clinical analysis systems. Sensors for measurement of blood gases, electrolytes, and metabolites are particularly well suited for incorporation into automated, point-of-care, and critical-care analyzers (see Chapters 11, 12, and 27 respectively), because of their ease of use, low maintenance, and ability to measure clinically important analytes in undiluted blood.[51] When integrated into chromatographic systems (see Chapter 6), electrochemical detectors provide a very sensitive and selective means to detect a variety of other analytes, such as therapeutic drugs, neurotransmitters, glutathione, and homocysteine. Also, electrochemical detection has been applied successfully for monitoring coagulation reactions, detecting toxic lead in blood samples, and developing novel ultrasensitive immunoassay schemes. When bioelements are integrated with electrodes, the resultant biosensors further expand the analytical capabilities of such devices. In addition, the development and application of "optodes," based on some of the same selective chemistries used in electrochemical devices, provide yet another analytical tool for measuring blood gases and electrolytes.

In this chapter, the fundamental electrochemical principles of potentiometry, voltammetry and/or amperometry, conductance, and coulometry will be summarized and clinical applications presented. Next, optodes and biosensors will be discussed. The chapter concludes with a discussion of in vivo and minimally invasive sensors.

*The authors gratefully acknowledge the original contributions of Drs. Richard A. Durst and Ole Siggard-Andersen on which portions of this chapter are based.

POTENTIOMETRY AND ION-SELECTIVE ELECTRODES

Potentiometry is widely used clinically for the measurement of pH, PCO_2 and electrolytes (Na^+, K^+, Cl^-, Ca^{2+}, Mg^{2+}, Li^+) in whole blood, serum, plasma and urine, and as the basis for some biosensors for metabolites of clinical interest.

Basic Concepts

Potentiometry is the measurement of an electrical potential difference between two electrodes (half-cells) in an electrochemical cell (Figure 4-1) when the cell current is zero (galvanic cell). Such a cell consists of two electrodes (electron or metallic conductors) that are connected by an electrolyte solution (ion conductor). An *electrode,* or *half-cell,* consists of a single metallic conductor that is in contact with an electrolyte solution. The ion conductors can be composed of one or more phases that are either in direct contact with each other or separated by membranes permeable only to specific cations or anions (see Figure 4-1). One of the electrolyte solutions is the unknown or test solution; this solution may be replaced by an appropriate reference solution for calibration purposes. By convention, the cell notation is shown so that the left electrode (M_L) is the reference electrode; the right electrode (M_R) is the *indicator (measuring) electrode* (see later equation 3).[9]

The *electromotive force* (*E* or EMF) is defined as the maximum difference in potential between the two electrodes (right minus left) obtained when the cell current is zero. The cell potential is measured using a *potentiometer,* of which the common pH meter is a special type. The *direct-reading potentiometer* is a voltmeter that measures the potential across the cell (between the two electrodes); however, to obtain an accurate potential measurement, it is necessary

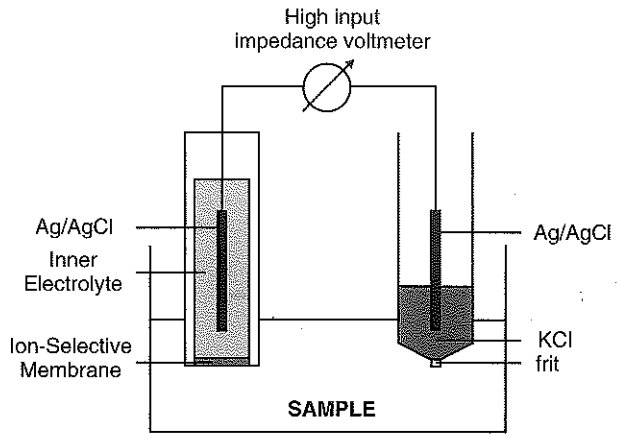

Figure 4-1 Schematic of ion-selective membrane electrode-based potentiometric cell.

that no current flow through the cell. This is accomplished by incorporating a high resistance within the voltmeter (input impedance $>10^{12}\,\Omega$). Modern direct-reading potentiometers are accurate and can be modified to provide direct digital display or printouts.

Within any one conductive phase, the potential is constant as long as the current flow is zero. However, a potential difference arises between two different phases in contact with each other. The overall potential of an electrochemical cell is the sum of all the potential gradients that exist between different phases of the cell. The potential of a single electrode with respect to the surrounding electrolyte and the absolute magnitude of the individual potential gradients between the phases are unknown and cannot be measured. Only the *potential differences* between two electrodes (half-cells) can be measured. The potential gradients can be classified as (1) redox potentials, (2) membrane potentials, or (3) diffusion potentials. Generally, it is possible to devise a cell in such a manner that all the potential gradients except one are constant. This potential can then be related to the activity of a specific ion of interest (e.g., H^+ or Na^+).

Types of Electrodes

Many different types of electrodes are used for potentiometric applications. They include redox, ion-selective membrane (glass and polymer), and PCO_2 electrodes.

Redox Electrodes

Redox potentials are the result of chemical equilibria involving electron transfer reactions:

$$\text{Oxidized form (Ox)} + ne^- \longleftrightarrow \text{Reduced form (Red)} \quad (1)$$

where n represents the number of electrons involved in the reaction. Any substance that accepts electrons is an *oxidant* (Ox), and any substance that donates electrons is a *reductant* (Red). The two forms, Ox and Red, represent a redox couple (conjugate redox pair). Usually, homogeneous redox processes take place only between two redox couples. In such cases, the electrons are transferred from a reductant (Red_1) to an oxidant (Ox_2). In this process, Red_1 is oxidized to its conjugate Ox_1, whereas Ox_2 is reduced to Red_2:

$$Red_1 + Ox_2 \longleftrightarrow Ox_1 + Red_2 \quad (2)$$

In an electrochemical cell, electrons may be accepted from or donated to an inert metallic conductor (e.g., platinum). A reduction process tends to charge the electrode positively (remove electrons), and an oxidation process tends to charge the electrode negatively (add electrons). By convention, a heterogeneous redox equilibrium (equation 2) is represented by the cell

$$M_L|\text{Red}_1 - \text{Ox}_1 :: \text{Ox}_2 - \text{Red}_2|M_R \quad (3)$$

A positive potential ($E > 0$) for this cell signifies that the cell reaction proceeds spontaneously from left to right; $E < 0$ signifies that the reaction proceeds from right to left; and $E = 0$ indicates that the two redox couples are at mutual equilibrium.

The *electrode potential* (reduction potential) for a redox couple is defined as the couple's potential measured with respect to the standard hydrogen electrode, which is set equal to zero (see hydrogen electrode later). This potential, by convention, is the electromotive force of a cell, where the standard hydrogen electrode is the reference electrode (left electrode) and the given half-cell is the indicator electrode (right electrode). The reduction potential for a given redox couple is given by the Nernst equation:

$$E = E^\circ - \frac{N}{n} \times \log\frac{a_{\text{Red}}}{a_{\text{Ox}}} = E^\circ - \frac{0.0592V}{n} \times \log\frac{a_{\text{Red}}}{a_{\text{Ox}}} \quad (4)$$

where

E = electrode potential of the half-cell
E° = standard electrode potential when $a_{\text{Red}}/a_{\text{Ox}} = 1$
n = number of electrons involved in the reduction reaction
$N = (R \times T \times \ln 10)/F$ (the Nernst factor if n = 1)
$N = 0.0592$ V if $T = 298.15$ K (25 °C)
$N = 0.0615$ V if $T = 310.15$ K (37 °C)
R = gas constant (= 8.31431 Joules × K^{-1} × mol^{-1})
T = absolute temperature (unit: K, kelvin)
F = Faraday constant (= 96,487 Coulombs × mol^{-1})
ln 10 = natural logarithm of 10 = 2.303
a = activity
$a_{\text{Red}}/a_{\text{Ox}}$ = product of mass action for the reduction reaction

Redox electrodes currently in use are either (1) inert metal electrodes immersed in solutions containing redox couples or (2) metal electrodes whose metal functions as a member of the redox couple.

Inert Metal Electrodes

Platinum and *gold* are examples of inert metals used to record the redox potential of a redox couple dissolved in an electrolyte solution. The *hydrogen electrode* is a special redox electrode for pH measurement. It consists of a platinum or gold electrode that is electrolytically coated (platinized) with

highly porous platinum (platinum black) to catalyze the electrode reaction.

$$H^+ + e^- \longleftrightarrow \frac{1}{2}H_2 \quad (5)$$

The electrode potential is given by

$$E = E^\circ - N \times \log\frac{(f_{H_2})^{1/2}}{a_{H^+}} \quad (6)$$

or

$$E = E^\circ - N \times \left[\log(f_{H_2})^{1/2} - \log a_{H^+}\right] \quad (7)$$

where

$E^\circ = 0$ at all temperatures (by convention)
f_{H_2} = fugacity of hydrogen gas
a_{H^+} = activity of hydrogen ions
$-\log a_{H^+}$ = negative log of the H^+ activity (pa_{H^+} or pH)

When the partial pressure of hydrogen (PH_2) in the solution (and hence f_{H_2}) is maintained constant by bubbling hydrogen through the solution, the potential is a linear function of $\log a_{H^+}$ (= −pH). In the *standard hydrogen electrode (SHE),* the electrolyte consists of an aqueous solution of hydrogen chloride with a_{HCl} equal to 1.000 (or c_{HCl} = 1.2 mol/L) in equilibrium with a gas phase and with f_{H_2} equal to 1.000 (or PH_2 = 101.3 kPa = 1 atm). The SHE is also used as a reference electrode.

Metal Electrodes Participating in Redox Reactions

The silver-silver chloride electrode is an example of a metal electrode that participates as a member of a redox couple. The silver-silver chloride electrode consists of a silver wire or rod coated with $AgCl_{(s)}$ that is immersed in a chloride solution of constant activity; this sets the half-cell potential. The Ag/AgCl electrode is itself considered a potentiometric electrode, as its phase boundary potential is governed by an oxidation-reduction electron transfer equilibrium reaction that occurs at the surface of the silver:

$$AgCl_{(solid)} + e^- \longleftrightarrow Ag^\circ_{(solid)} + Cl^- \quad (8)$$

The Nernst equation for the reference half-cell potential of an Ag/AgCl reference electrode can be written as:

$$E_{Ag/AgCl} = E^0_{Ag/AgCl} + \frac{RT}{nF} \times \ln\frac{a_{AgCl}}{a_{Ag}a_{Cl^-}} \quad (9)$$

Since AgCl and Ag are both solids, their activities are equal to unity ($a_{AgCl} = a^0_{Ag} = 1$). Therefore, from equation 9, the half-cell potential is controlled by the activity of chloride ion in solution (a_{Cl^-}) contacting the electrode.

The Ag/AgCl electrode is used both as an internal reference element in potentiometric ISEs, and as an external reference electrode half-cell of constant potential, required to complete a potentiometric cell (see Figure 4-1). In both cases, the Ag/AgCl electrode must be in equilibrium with a solution of constant chloride ion activity.

The Ag/AgCl element of the external reference electrode half-cell is in contact with a high-concentration solution of a soluble chloride salt. Saturated potassium chloride is commonly used. A porous membrane or frit is frequently employed to separate the concentrated KCl from the sample solution. The frit serves both as a mechanical barrier to hold the concentrated electrolyte within the electrode and as a diffusional barrier to prevent proteins and other species in the sample from coming into contact with the internal Ag/AgCl element, that could poison and alter its potential. The interface between two dissimilar electrolytes (concentrated KCl/calibrator or sample) occurs within the frit and develops the liquid-liquid junction potential (E_j), a source of error in potentiometric measurements. The difference in liquid-liquid junction potential between calibrator and sample (residual liquid junction potential) is responsible for this error and can be minimized and usually neglected in practice if the compositions of the calibrating solutions are matched as closely as possible to the sample with respect to ionic content and ionic strength. An equitransferant electrolyte at high concentration as the reference electrolyte further helps to minimize the residual liquid junction potential. Potassium chloride at a concentration ≥2 mol/L is preferred. Differences of approximately −2% in the measurement of sodium by ISEs have been demonstrated when the KCl concentration in the reference electrolyte is lowered from 3 to 0.5 mol/L.[24] The magnitude of the residual liquid junction potential may also be estimated by the Henderson equation[82] with sufficient knowledge of ionic activities, ionic charges, and ionic mobilities for each electrolyte on both sides of the junction and the temperature. Using this estimate, a correction to the overall cell potential may be applied.

The presence of erythrocytes in the sample may also affect the magnitude of the residual liquid junction potential in a less predictable manner. For example, erythrocytes in blood of normal hematocrit are estimated to produce approximately 1.8 mmol/L positive error in the measurement of sodium by ISEs when an open, unrestricted liquid-liquid junction is used.[11] This bias may be minimized if a restrictive membrane or frit is used to modify the liquid-liquid junction.

The *calomel electrode* consists of mercury covered by a layer of calomel (Hg_2Cl_2), which is in contact with an electrolyte solution containing Cl^-. Calomel electrodes are frequently used as reference electrodes for pH measurements using glass pH electrodes.

Ion-Selective Electrodes

Membrane potentials are caused by the permeability of certain types of membranes to selected anions or cations. Such membranes are used to fabricate ISEs that selectively interact with a single ionic species. The potential produced at the membrane-sample solution interface is proportional to the logarithm of the ionic activity or concentration of the ion in question. Measurements with ISEs are simple, often

rapid, nondestructive, and applicable to a wide range of concentrations.

The ion-selective membrane is the "heart" of an ISE as it controls the selectivity of the electrode. Ion-selective membranes are typically composed of glass, crystalline, or polymeric materials. The chemical composition of the membrane is designed to achieve an optimal permselectivity toward the ion of interest. In practice, other ions exhibit finite interaction with membrane sites and will display some degree of interference for determination of an analyte ion. In clinical practice, if the interference exceeds an acceptable level, a correction is required.

The Nicolsky-Eisenman equation describes the selectivity of an ISE for the ion of interest over interfering ions:

$$E = E^{\circ} + \left(\frac{2.303RT}{z_i F}\right)\log\left(a_i + \sum K_{i/j} a_j^{zi/zj}\right) \qquad (10)$$

where

a_i = activity of the ion of interest
a_j = activity of the interfering ion
$K_{i/j}$ = selectivity coefficient for the primary ion over the interfering ion. Low values indicate good selectivity for the analyte "i" over the interfering ion "j".
z_i = charge of primary ion
z_j = charge of interfering ion

All other terms are identical to those in the Nernst equation (equation 4).

There are various approaches for determining the selectivity of an ISE for a primary ion over an interfering ion.[7,12] A straightforward approach is the *separate solution method*, where the potential of an ISE is determined in solutions of the primary and interfering ions separately but at equal ionic activities. The selectivity coefficient is then calculated as:

$$\log K_{i/j} = \frac{E_j - E_i}{\frac{2.303RT}{nF}} + \left(1 - \frac{z_i}{z_j}\right)\log a_i \qquad (11)$$

Most ISEs used in clinical practice have sufficient selectivity and do not require correction for interfering ions. Oesch et al have published required ISE selectivity coefficients for ions commonly measured in clinical chemistry over other ions found in blood.[69] Table 4-1 shows required selectivity coefficients for the measurement of cations of interest in clinical chemistry over potentially interfering cations, assuming an acceptable maximum interference of 1% for the ion of interest.

Glass membrane and polymer membrane electrodes are two types of ISEs that are commonly used in clinical chemistry applications.

TABLE 4-1 Required Selectivities for Cation-Selective ISEs for Whole Blood, Plasma, and Serum Measurements

Primary Ion (i)	Required Selectivity Coefficient ($\log K_{i/j}$) for Interfering Cation (j)					
	H^+	Li^+	Na^+	K^+	Mg^{2+}	Ca^{2+}
H^+	—	−6.5	−8.5	−7.0	−7.7	−7.7
Li^{+*}	2.1	—	−4.3	−2.8	−3.5	−3.6
Na^+	4.4	−0.1	—	−0.6	−1.2	−1.3
K^+	2.8	−1.7	−3.6	—	−2.8	−2.9
Mg^{2+}	8.9	0.1	−3.9	−0.9	—	−2.4
Ca^{2+}	9.3	0.4	−3.6	−0.6	−1.9	—

*Assumes a therapeutic range for Li^+ between 0.7 and 1.5 mmol/L.

The Glass Electrode

Glass membrane electrodes are employed to measure pH and Na^+, and as an internal transducer for PCO_2 sensors. The H^+ response of thin glass membranes was first demonstrated in 1906 by Cremer.[22] In the 1930s, practical application of this phenomenon for measurement of acidity in lemon juice was made possible by the invention of the pH meter by Arnold Beckman.[9] Glass electrode membranes are formulated from melts of silicon and/or aluminum oxide mixed with oxides of alkaline earth or alkali metal cations. By varying the glass composition, electrodes with selectivity for H^+, Na^+, K^+, Li^+, Rb^+, Cs^+, Ag^+, Tl^+ and NH_4^+ have been demonstrated.[29] However, glass electrodes for H^+ and Na^+ are today the only types with sufficient selectivity over interfering ions to allow practical application in clinical chemistry. A typical formulation for H^+ selective glass is: 72% SiO_2; 22% Na_2O; 6% CaO, that has a selectivity order of $H^+ >>> Na^+ > K^+$. This glass membrane has sufficient selectivity for H^+ over Na^+ to allow error free measurements of pH in the range of 7.0 to 8.0 ($[H^+] = 10^{-7}$ to 10^{-8} mol/L) in the presence of >0.1 mol/L Na^+. Glass pH electrodes with selectivity coefficients ($K_{H/Na}$) over Na^+ of 10^{-7} and better have been realized. By altering slightly the formulation of the glass membrane to: 71% SiO_2; 11% Na_2O; 18% Al_2O_3 its selectivity order becomes $H^+ > Na^+ > K^+$. Thus, the preference of the glass membrane for H^+ over Na^+ is greatly reduced, resulting in a practical sensor for Na^+ at pH values typically found in blood.[28]

Polymer Membrane Electrodes

Polymer membrane ISEs are employed for monitoring pH and for measuring electrolytes, including K^+, Na^+, Cl^-, Ca^{2+}, Li^+, Mg^{2+}, and CO_3^{2-} (for total CO_2 measurements). They are the predominant class of potentiometric electrodes used in modern clinical analysis instruments.

The mechanism of response of these ISEs falls into three categories: (1) charged, dissociated ion-exchanger; (2) charged associated carrier, and (3) the neutral ion carrier (ionophore).[6,13] An early charged associated ion-exchanger type ISE for Ca^{2+} was developed and commercialized for clinical application in the 1960s. This electrode was based on the Ca^{2+}-selective ion-exchange/complexation properties of 2-ethylhexyl phosphoric acid dissolved in dioctyl phenyl phosphonate (charged associated carrier).[34] A porous mem-

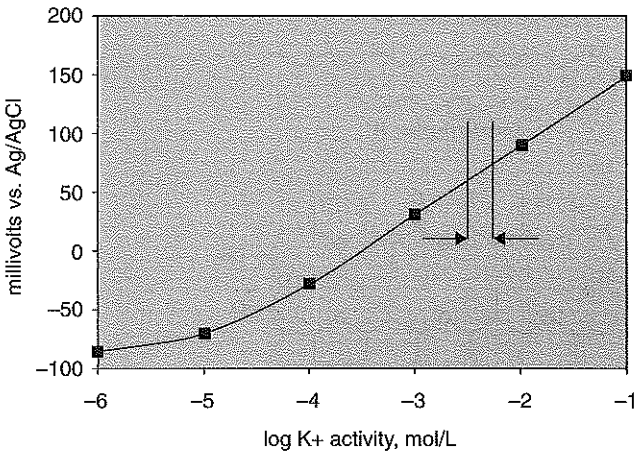

Figure 4-2 Typical EMF response of potassium selective membrane electrode to changes in the activity of potassium in the sample solution. Bracketed interval represents the normal reference interval of potassium concentration in blood. *(From D'Orazio P. In: Clinical chemistry laboratory management and clinical correlations, Lewendrowski K, ed. Philadelphia: Lippincott, Williams and Wilkins, 2002: 455.)*

brane was impregnated with this cocktail and mounted at the end of an electrode body. This type sensor was referred to as the "liquid membrane" ISE. Later a method was devised where these ingredients could be cast into a plasticized poly(vinyl chloride) (PVC) membrane, that was more rugged and convenient to use than its wet liquid predecessor. This same approach is still used today to formulate PVC-based ISEs for clinical use.[66]

A major breakthrough in the development and routine application of PVC type ISEs was the discovery by Simon and co-workers that the neutral antibiotic valinomycin could be incorporated into organic liquid membranes (and later plasticized PVC membranes), resulting in a sensor with high selectivity for K^+ over Na^+ ($K_{K/Na} = 2.5 \times 10^{-4}$).[75] The K^+ ISE based on valinomycin was the first example of a neutral carrier ISE and is extensively used today for the routine measurement of K^+ in blood. Figure 4-2 shows the response of the valinomycin-based K^+ ISE in the presence of physiological levels of Na^+, Ca^{2+}, and Mg^{2+}. The wide linear range of this ISE over three orders of magnitude makes it suitable for the measurement of K^+ in blood and urine. The K^+ range in blood is only a small portion of the electrode linear range and is spanned by a total ΔEMF of about 9 mV. Interference from other cations, seen as deviation from linearity, is not apparent at K^+ activities $>10^{-4}$ mol/L. Other, less selective polymer-based ISEs (e.g., for the measurement of Mg^{2+} and Li^+), are subject to interference from Ca^{2+}/Na^+, and Na^+, respectively, requiring simultaneous determination and correction for the presence of significant levels of interfering ions.[63,77]

Studies regarding the relationship between molecular structure and ionic selectivity have resulted in the development of polymer-based ISEs using a number of naturally occurring and synthetic ionophores, with sufficient selectivity for application in clinical analysis. The chemical structures of several of these neutral ionophores are illustrated in Figure 4-3.

Dissociated anion exchanger-based electrodes employing lipophilic quaternary ammonium salts as active membrane components are also still used commercially for the determination of Cl^- in whole blood, serum, and plasma despite some limitations.[55] Selectivity for this type of ISE is controlled by extraction of the ion into the organic membrane phase and is a function of the lipophilic character of the ion (since, unlike the carriers described above, there is no direct binding interaction between the exchanger site and the anion in the membrane phase). Thus, the selectivity order for Cl^- ISE based on an anion exchanger is fixed as $R^- > ClO_4^- > I^- > NO_3^- > Br^- > Cl^- > F^-$. The application of the Cl^- ion-exchange electrode is therefore limited to samples without significant concentrations of anions more lipophilic than Cl^-. Blood samples containing salicylate or thiocyanate, for example, will produce positive interference for the measurement of Cl^-. Repeated exposure of the electrode to the anticoagulant heparin will lead to loss of electrode sensitivity toward Cl^- because of extraction of the negatively charged heparin into the membrane. Indeed, this extraction process has been used successfully to devise a method to detect heparin levels in blood by potentiometry.[58]

High selectivity for carbonate anion can be achieved using a neutral carrier ionophore possessing trifluoroacetophenone groups doped within a polymeric membrane.[53,83] Such ionophores form negatively charged adducts with carbonate anions, and the resulting electrodes have proven useful in commercial instruments for determination of total carbon dioxide in serum/plasma, after dilution of the blood to a pH value in the range of 8.5 to 9.0, where a significant fraction of total carbon dioxide will exist as carbonate anions.

A typical formulation of a PVC membrane ISE used in clinical instrumentation is:

1 to 3 wt% ionophore
~64 wt% plasticizer
~30 wt% PVC
<1 wt% additives

The plasticizer is crucial in controlling the polarity of the membrane and thus, along with the ionophore, plays a pivotal role in determining the selectivity of the membrane toward the ion of interest. A large lipophilic anion (e.g., tetraphenylborate derivative) is often included as an additive for preparation of cation selective ISE membranes. This anion serves as a counteranion for the cation of interest as it is extracted into the membrane phase forming a positively charged complex with the neutral ionophore. However, it is the ratio of bound to unbound ionophore sites at the membrane surface that determines the magnitude of the phase boundary potential generated by the ISE membrane.[3] Thus, the selective response to the activity of the ion of interest is an interfacial property of the given ISE membrane.

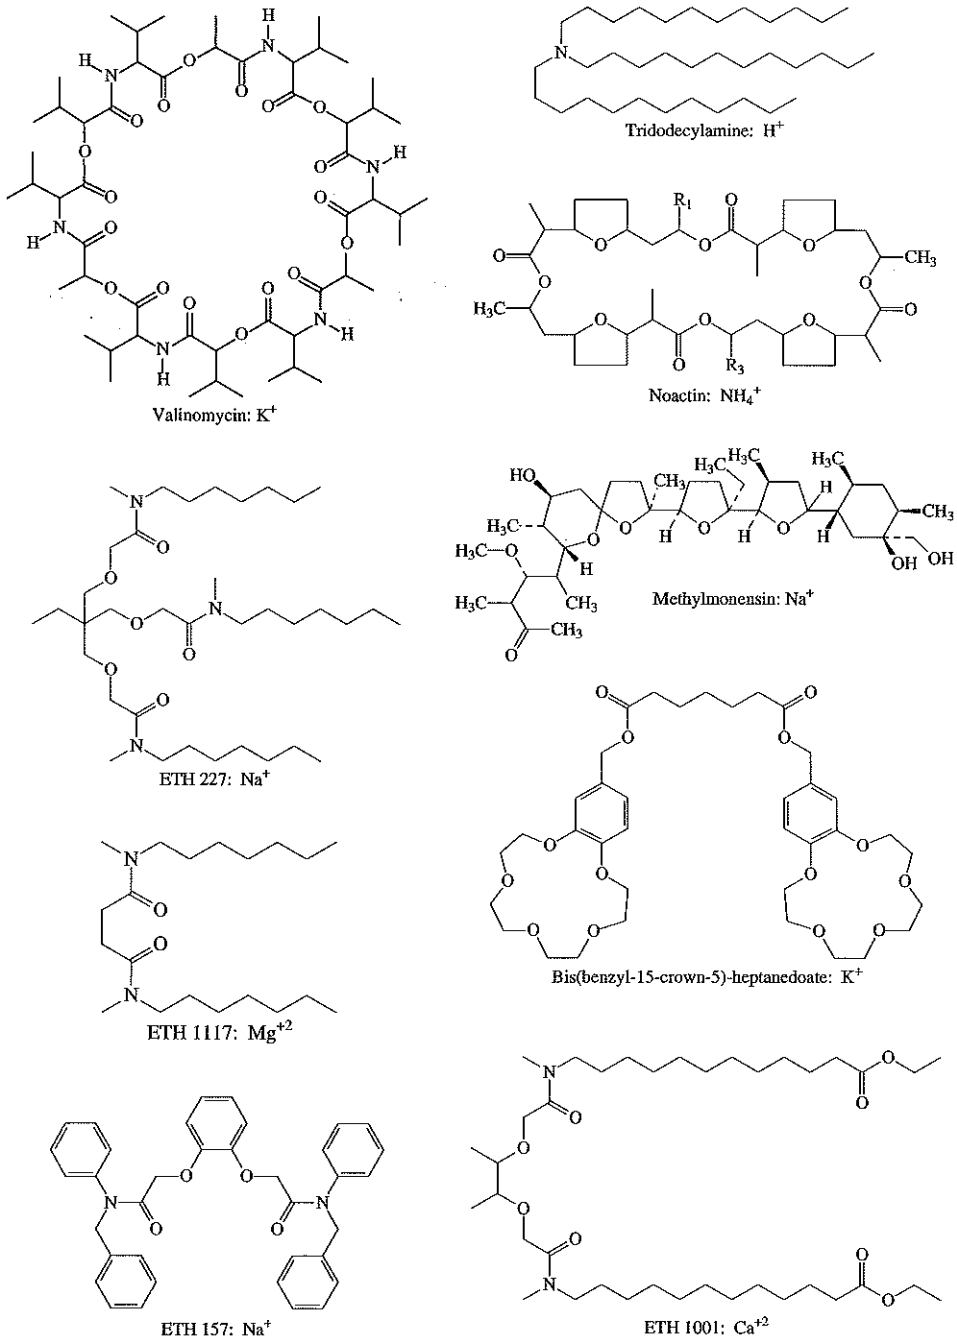

Figure 4-3 Structures of common ionophores used to fabricate polymer membrane type ISEs for clinical analysis.

Studies have demonstrated that the ultimate detection limits of polymer membrane type ISEs are controlled in part by the leakage of analyte ions, from the internal solution to the outer surface of the membrane, and into the sample phase in close contact with the membrane.[61] Hence, much lower limits of detection can often be achieved by decreasing the concentration of the primary analyte ion within the internal solution of the electrode. Further, this leakage of analyte ions, coupled with an ion-exchange process at the membrane sample interface when assessing the selectivity of the membrane over other ions, can often yield a measured potentiometric selectivity coefficient that underestimates the true selectivity of the membrane. To determine "unbiased" selectivity coefficients by the separate solution method, the membrane should not be exposed to the analyte ion for extended periods of time, and the concentration of analyte ion in the internal solution should be low.[8]

Electrodes for PCO_2

Electrodes have been developed to measure PCO_2 in body fluids. The first PCO_2 electrode, developed in the 1950s by Stow and Severinghaus, used a glass pH electrode as the

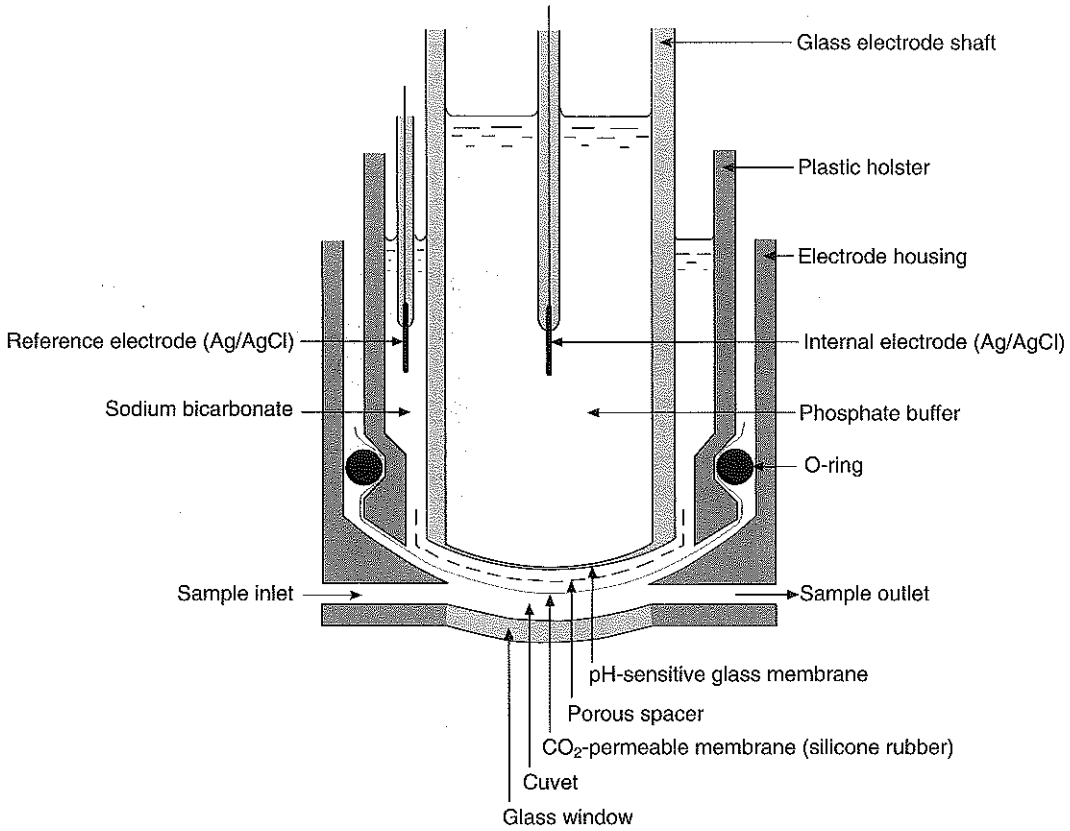

Figure 4-4 Schematic of Severinghaus style PCO_2 sensor used to monitor CO_2 levels in blood samples. *(From Siggard-Andersen O. The acid-base status of the blood. 4th ed. Baltimore: Williams & Wilkins, 1974: 172.)*

internal element in a potentiometric cell for measurement of the partial pressure of carbon dioxide.[4] This important development paved the way for commercial availability of the three-channel blood analyzer (pH, PCO_2, PO_2) to give the complete picture of the oxygenation and acid-base status of blood.

Figure 4-4 shows a diagram of a typical Severinghaus style electrode for PCO_2. A thin membrane (~20 μm), permeable to only to gases and water vapor, is in contact with the sample. Membranes of silicone rubber, Teflon, and other polymeric materials are suitable for this purpose. On the opposite side of the membrane is a thin electrolyte layer consisting of a weak bicarbonate salt (about 5 mmol/L) and a chloride salt. A pH electrode and Ag/AgCl reference electrode are in contact with this solution. The PCO_2 electrode is a self-contained potentiometric cell. Carbon dioxide gas from the sample or calibration matrix diffuses through the membrane and dissolves in the internal electrolyte layer. Carbonic acid is formed and dissociates, shifting the pH of the bicarbonate solution in the internal layer:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \qquad (12)$$

and

$$\Delta \log PCO_{2(\text{sample})} \approx \Delta pH_{(\text{internal layer})} \qquad (13)$$

The relationship between the sample PCO_2 and the signal generated by the internal pH electrode is logarithmic and governed by the Nernst equation. The electrode may be calibrated using precision gas mixtures or by solutions with stable PCO_2 concentrations. While Severinghaus style electrodes for PCO_2 have gained widespread use in modern blood gas analyzers, the format in which such sensors may be constructed is limited by the size, shape, and ability to fabricate the internal pH sensitive element.

A slightly different potentiometric cell for PCO_2 is shown in Figure 4-5. This cell arrangement uses two PVC type pH selective electrodes in a differential mode. The electrode membranes contain a lipophilic amine type neutral ionophore that exhibits very high selectivity for H^+ (see Figure 4-3). One electrode has an internal layer, which is buffered, while the other is unbuffered, consisting of a low concentration of bicarbonate salt. Carbon dioxide gas from the sample or calibration matrix diffuses across the outer H^+-selective PVC membranes of both sensors. On the unbuffered side, CO_2 diffusion produces a potential shift at the internal interface of the pH responsive membrane proportional to sample PCO_2 concentration. The signal at the electrode with the buffered internal layer is unaffected by CO_2 that diffuses across the membrane. Consequently, one half of the sensor responds to pH alone, while the other half responds to both pH and PCO_2. The signal difference

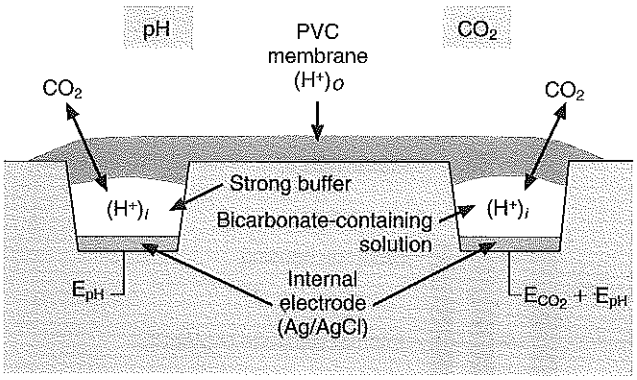

Figure 4-5 Differential planar PCO_2 potentiometric sensor design, based on two identical polymeric membrane pH electrodes, but with different internal reference electrolyte solutions. Both pH sensing membranes are prepared with H^+-selective ionophore.

between the two electrodes cancels any contribution of sample pH to the overall measured cell potential. The differential signal is proportional only to PCO_2. Unlike the traditional Severinghaus style electrode, this differential potentiometric cell PCO_2 sensor has been commercialized in a planar format and is more easily adaptable to mass production in sensor arrays.[14]

Direct Potentiometry by ISE—Units of Measure and Reporting for Clinical Applications

Classical analytical methods such as flame photometry for the measurement of electrolytes provide the total *concentration (c)* of a given ion in the sample, usually expressed in units of millimoles of ion per liter of sample (mmol/L). *Molality (m)* is a measure of the moles of ion per mass of water (mmol/kg) in the sample. Using the sodium ion as an example, the relationship between concentration and molality is given by:

$$c_{Na^+} = m_{Na^+} \times \rho H_2O \qquad (14)$$

where ρH_2O is the mass concentration of water in kg/L. For normal blood plasma, the mass concentration of water is approximately 0.93 kg/L, but in specimens with elevated lipids or protein, the value may be as low as 0.8 kg/L. In these specimens, the difference between concentration and molality may be as great as 20%. A significant advantage of direct potentiometry by ISE for the measurement of electrolytes is that the technique is sensitive to molality and is therefore not affected by variations in the concentration of protein or lipids in the sample. Techniques such as flame photometry and other photometric methods requiring sample dilution are affected by the presence of protein and lipids. In these methods, only the water phase of the sample is diluted, producing results lower than molality as a function of the concentration of protein and lipids in the sample. Thus there is a risk for errors, such as a falsely low Na^+ concentration (pseudohyponatremia), in cases of extremely elevated protein and lipid concentrations.[2]

In addition to the difference between molality and concentration, measurement of ions by direct potentiometry provides yet another unit of measurement known as *activity (a)*, the concentration of free, unbound ion in solution. Unlike methods sensitive to ion concentration, ISEs do not sense the presence of complexed or electrostatically "hindered" ions in the sample. The relationship between activity and concentration using, again, sodium ion as an example, is expressed as:

$$a_{Na^+} = \gamma_{Na^+} \times c_{Na^+} \qquad (15)$$

where γ is a dimensionless quantity known as the activity coefficient. The activity coefficient is primarily dependent on ionic strength of the sample as described by the Debye-Huckel equation:

$$\log \gamma = -\frac{(A \times z^2 \times I^{1/2})}{1 + B \times a \times I^{1/2}} \qquad (16)$$

where A and B are temperature-dependent constants ($A = 0.5213$ and $B = 3.305$ in water at 37 °C), a is the ion size parameter for a specific ion, and I is the ionic strength ($I = 0.5\ \Sigma m \times z^2$, where z is the charge number of the ions). Equation 16 shows that a decrease in the activity coefficient occurs with an increase in ionic strength. This effect is more pronounced when the charge (z) of the ion is high. Activity coefficients for ions in biological fluids, such as blood and serum, are difficult to calculate with accuracy because of the uncertain contribution of macromolecular ions, such as proteins, to the overall ionic strength. However, assuming that the normal ionic strength of blood plasma is 0.160 mol/kg, estimates of activity coefficients at 37 °C are: $Na^+ = 0.75$, $K^+ = 0.74$, and $Ca^{2+} = 0.31$. Referring to equation 15, activity and concentration will differ greatly in samples of physiological ionic strength, especially for divalent ions.

Physiologically, ionic activity is assumed to be more relevant than concentration when considering chemical equilibria or biological processes. Practically, however, ionic concentration is the more familiar term in clinical practice, forming the basis of reference intervals and medical decision levels for electrolytes. Early in the evolution of ISEs as practical tools in clinical chemistry, it was decided that changing clinical reference intervals to a system based on activity instead of concentration was impractical and carried the risk for clinical misinterpretation. A pragmatic approach for using ISEs in modern analyzers without changing established concentration-based reference intervals is to formulate calibration solutions with ionic strengths and ionic compositions as close as possible to that of normal blood plasma. In this way, the activity coefficient of each ion in the calibrating solutions approximates that in the sample matrix, allowing calibration and measurement of electrolytes in units of concentration instead of activity.[71]

A typical set of solutions for multi-ISE calibration in an analyzer is shown in Table 4-2. Two points are used to calibrate each ISE. The difference in the cell potential generated

TABLE 4-2 Example of Two-Level Calibrating Solutions for Measurement of pH and Electrolytes by Direct Potentiometry*

Analyte	Calibration Point (mmol/L)	Slope Point (mmol/L)	Expected Signal Δ (millivolts)
Na^+	140	110	6.6
K^+	4.0	8.0	18
Ca^{2+}	1.25	2.50	9
Cl^-	100	80	6
pH	7.38 (pH units)	6.84 (pH units)	32.4

*Ionic strength adjusted to 160 mmol/kg with buffer salts and inert electrolytes.

by these two solutions (ΔE) is used to calculate the response slope of the cell (slope = (ΔE/Δlog c) where c is the concentration of ion in each calibrating solution, substituted for activity. The standard electrode potential, E^0, is calculated as the y-intercept. Determination of ion concentration in an unknown sample is then a straightforward solution of the Nickolsky-Eisenman equation (equation 10), after measuring the cell potential generated by the sample.

Calibration of the cell is in units of concentration; however, as mentioned above, direct potentiometry is sensitive to the molality of the ion, which is related to concentration by the water content of the sample (equation 14). The water content of aqueous calibrating solutions shown in Table 4-2 is approximately 0.99 kg/L. The water content of normal blood plasma is ~0.93 kg/L. Molality is 7% greater than concentration in this normal plasma specimen. The direct potentiometric cell will report results approximately 6% greater than the concentration in normal specimens because of this difference in water content between sample and calibrator (0.99/0.93 = 1.06). Direct potentiometry presents an advantage in that the technique is not affected by the presence of protein and lipids in the sample; however, the application of clinical reference intervals based on concentration again poses a risk for confusion and clinical misinterpretation. Most manufacturers of electrolyte measurement systems have overcome this problem in a practical way by following National Committee for Clinical Laboratory Standards (NCCLS) guidelines recommending the use of correlation factors to standardize ISE measurements to units of concentration. These factors may be obtained by standardizing the ISE measurement to certified reference materials based on human serum, with electrolyte values assigned in units of concentration.[42,68,86] The appropriate correlation factors are then applied to sample calculations using algorithms resident in the instrument software.

VOLTAMMETRY/AMPEROMETRY

Voltammetric and amperometric techniques are among the most sensitive and widely applicable of all electroanalytical methods.

Basic Concepts

In contrast to potentiometry, voltammetric and amperometric methods are based on electrolytic electrochemical cells, in which an external voltage is applied to a polarizable working electrode (measured versus a suitable reference electrode: $E_{appl} = E_{work} - E_{ref}$), and the resulting cathodic (for analytical reductions) or anodic (for analytical oxidations) current of the cell is monitored and is proportional to the concentration of analyte present in the test sample. Current only flows if E_{appl} is greater than a certain voltage (decomposition voltage), determined by the thermodynamics for a given redox reaction of interest ($Ox + ne^- \leftrightarrow Red$; defined by the E^0 value for that reaction (standard reduction potential)), and the kinetics for heterogeneous electron transfer at the interface of the working electrode. Often, slow kinetics of electron transfer for the redox reaction on a given inert working electrode (Pt, carbon, gold, etc.) mandates use of a much more negative (for reductions) or positive (for oxidations) E_{appl} than predicted based merely on the E^0 for a given redox reaction. This is called an overpotential (η). Regardless of whether or not an overpotential for electron transfer exists, in voltammetry/amperometry, a specific oxidation or reduction reaction occurs at the surface of the working electrode, and it is the charge transfer at this interface (current flow) that provides the analytical information.

For electrolytic cells that form the basis of voltammetric and amperometric methods:

$$E_{appl} = E_{cell} + \eta - iR_{cell} \qquad (17)$$

where E_{cell} is the thermodynamic potential between the working and reference electrode in the absence of an applied external voltage. When the external voltage is greater or less than this equilibrium potential, plus or minus any overpotential (η), then current will flow because of either an oxidation or reduction reaction at the working electrode. A voltammogram is simply the plot of observed current, i, vs. E_{appl} (Figure 4-6). In amperometry (see below), a fixed voltage is applied, and the resulting current is monitored. The amount of current is inversely related to the resistance of the electrolyte solution, and any "apparent" resistance that develops because of the mass transfer of the analyte species to the surface of the working electrode. Because the electrochemical reactions are heterogeneous, occurring only at the surface of the working electrode, the amount of current observed is also highly dependent on the surface area (A) of the working electrode.

When a potential is applied to a working electrode that will oxidize or reduce a species in the solution phase contacting the electrode, the electrochemical reaction causes the concentration of electroactive species to decrease at the

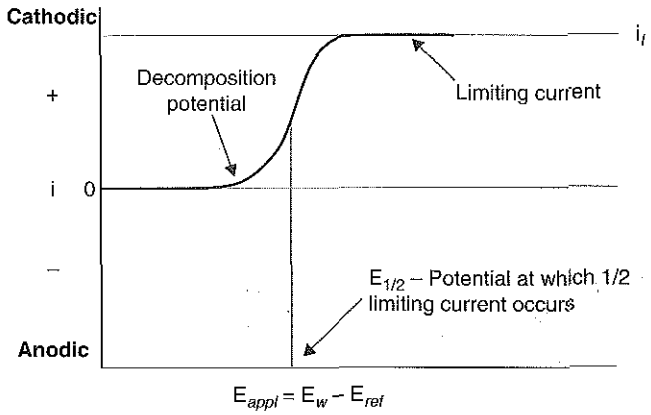

Figure 4-6 Illustration of the current vs. voltage curve (voltammogram) obtained for oxidized species (Ox) being reduced to Red at the surface of working electrode, as the E_{appl} is scanned more negative, and the solution is stirred to yield a steady-state response.

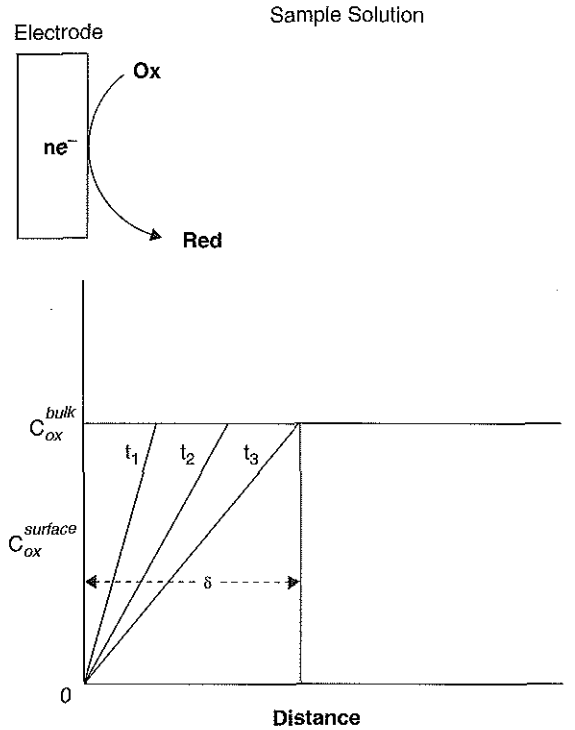

Figure 4-7 Concept of electrochemical reaction increasing the diffusion layer thickness (concentration polarization) of analyte via a reduction (or oxidation) at the surface of the working electrode. As time (t) increases, the diffusion layer thickness grows quickly to a value that is determined by degree of convection in the sample solution.

surface of the electrode (Figure 4-7), a process termed "concentration polarization." This in turn causes a concentration gradient of the analyte species between the bulk sample solution and the surface of the electrode.[32] When the bulk solution is stirred, the diffusion layer of analyte grows out from the surface of the electrode very quickly to a fixed distance controlled by how vigorously the solution is stirred. This diffusion layer is termed the Nernst layer and has a finite thickness (δ) after a relatively short time period (see Figure 4-7) when the solution is moving (convection). Voltammetry carried out in the presence of convection (either by stirring the solution, rotating the electrode, flowing solution by electrode, etc.) is called steady-state voltammetry. When the solution is not moving, the diffusion layer grows further and further with time (i.e., not constant), creating larger and larger δ values with time. This is termed nonsteady state voltammetry and often results in peak currents in i vs. E_{appl} plots for electrolytic cells.

In steady-state voltammetry, when the potential of the working electrode is scanned past a value that will cause an electrochemical reaction, the current will rise rapidly, and then level off to a near constant value, even as E_{appl} changes further. Figure 4-6 illustrates such a wave for a hypothetical reduction of an oxidized species (Ox) via an n electron reduction to a reduced species (Red). When the applied potential is much more negative than required, the current reaches a limiting value (termed the limiting current, i_l). This limiting current is proportional to the concentration of the electroactive species (Ox in this case) as expressed by the following equation:

$$i_l = nFA\left(\frac{D}{\delta}\right)C_{ox} \qquad (18)$$

where i is the measured current in amperes, n equals the number of electrons in the electrochemical reaction (reduction in this case), F is Faraday's constant (96,487 coulombs/mol), A is the electrochemical surface area of the working electrode (in cm^2) (assuming a planar electrode geometry), D is the diffusion coefficient (in cm^2/sec) of the electroactive species (Ox in this case), δ is the diffusion layer thickness (in cm), and C is the concentration of the analyte species in mol/cm^3. The D/δ term is often denoted as m_o, the mass transfer coefficient of the Ox species to the surface of the working electrode. Note that equation 18 indicates a linear relationship for limiting current and concentration. The exact same equation applies for detecting reduced species by an oxidation reaction at the working electrode. In this case, by convention, the resulting anodic current is considered a negative current. As shown in Figure 4-6, the potential of the working electrode that corresponds to a current that is exactly one half the limiting current is termed the $E_{1/2}$ value. This value is not dependent on analyte concentration. The $E_{1/2}$ is determined by the thermodynamics (E^0) of the given redox reaction, the solution conditions (e.g., if protons are involved in reaction, then the pH will influence the $E_{1/2}$ value), along with any overpotential caused by slow electron transfer, etc., at a particular working electrode surface. The $E_{1/2}$ values are indicative of a given species undergoing an electrochemical reaction under specified conditions; hence, the $E_{1/2}$ values enable one to distinguish one electroactive species from another in the same sample. If the

$E_{1/2}$ values for various species differ significantly (e.g., >120 mV), then measurements of several limiting currents in a given voltammogram can yield quantitative results for several different species simultaneously.

Electrochemical cells employed to carry out voltammetric or amperometric measurements can involve either a two or three electrode configuration. In the two electrode mode, the external voltage is applied between the working and a reference electrode, and the current monitored. Since the current must also pass through the reference electrode, such current flow can potentially alter the surface concentration of electroactive species that poises the actual half-cell potential of the reference electrode, changing its value by a concentration polarization process. For example, if an Ag/AgCl reference electrode were used in a cell in which a reduction reaction for the analyte occurs at the working electrode, then an oxidation reaction would take place at the surface of the reference electrode:

$$Ag^0 + Cl^- \rightarrow AgCl_{(s)} + 1e^- \qquad (19)$$

Hence, the activity/concentration of chloride ions near the surface of the electrode would decrease, which would make the potential of the reference electrode more positive than its true equilibrium value based on the actual activity of chloride ion in the reference half-cell since the Nernst equation for this half-cell is:

$$E_{Ag/AgCl} = E^0_{Ag/AgCl} - 0.059 \log\left(a^{surface}_{Cl^-}\right) \qquad (20)$$

Such concentration polarization of the reference electrode is prevented by maintaining the current density (J; amperes/cm^2) very low at the reference electrode. This is achieved in practice by making sure that the area of the working electrode in the electrochemical cell is much smaller than the surface area of the reference electrode; hence the total current flow will be limited by this much smaller area, and J values for the reference will be very small, as desired, to prevent concentration polarization.

To completely eliminate changes in reference electrode half-cell potentials, a three electrode potentiostat is often employed. In simple terms, the potentiostat applies a voltage to the working electrode, which is measured versus a reference electrode via a zero current potentiometric type measurement, but the current flow is between the working electrode and a third electrode, called the counter electrode. Thus if reduction takes place at the working electrode, oxidation would occur at the counter electrode; but no net reaction would take place at the surface of the reference electrode, since no current flows through this electrode. A potentiostat circuit is relatively simple to construct using modern operational amplifiers.

In voltammetric methods, the E_{appl} is varying via some waveform, to alter the working electrode potential as a function of time and the resulting current measured. The current change occurs at the decomposition potential range, which is hopefully specific for a given analyte. However, the location of the current response as a function of E_{appl} provides information on the nature of the species present (e.g., $E_{1/2}$) along with a concentration-dependent signal. This scan of E_{appl} can be linear (linear sweep voltammetry) or it can have more complex shapes that enable greatly enhanced sensitivity to be achieved for monitoring the concentration of a given electroactive species (e.g., normal pulsed voltammetry, differential pulse voltammetry, square wave voltammetry, etc.).[72] When a dropping mercury electrode (DME) is used, such voltammetric methods are considered polarographic methods of analysis.

Amperometric methods differ from voltammetry in that E_{appl} is fixed, generally at a potential value that occurs in the limiting current plateau region of the voltammogram and simply monitoring the resulting current, which will be proportional to concentration. Amperometry can be more sensitive than common voltammetric methods because background charging currents, which arise from changing the E_{appl} as a function of time in voltammetry, do not exist. Hence, when selectivity can be assured at a given E_{appl} value, amperometry may be preferred to voltammetric methods for more sensitive quantitative measurements.

Applications

Molecular oxygen is capable of undergoing several reduction reactions, all with a significant overpotentials at solid electrodes, such as Pt, Au, or Ag. For example, the following reaction:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \qquad (21)$$
$$\left(E^0 = +0.179 \quad vs \quad Ag/AgCl;1\,M\,Cl^-\right)$$

exhibits an $E_{1/2}$ at around −0.500 V on a Pt electrode (vs. a Ag/AgCl reference electrode), with a limiting current plateau beginning at approx. −0.600 V. This reaction can be used to monitor the partial pressure of oxygen (PO_2) in blood, which is the basis of the widely used Clark style amperometric oxygen sensor (Figure 4-8). This device employs a small area planar platinum electrode as a working electrode (encased in insulating glass or other material), and a Ag/AgCl reference electrode, typically a cylindrical design (Figure 4-8). This two electrode electrolytic cell is placed within a sensor housing, on which a gas permeable membrane (e.g., polypropylene, silicone rubber, Teflon, etc.) is held at the distal end. The inner working platinum electrode is pressed tightly against the gas-permeable membrane to create a thin film of internal electrolyte solution (usually buffer with KCl added). Oxygen in the sample can permeate across the membrane and be reduced in accordance with the above electrochemical reaction. An E_{appl} of −0.650 or −0.700 V vs. Ag/AgCl (within the limiting current regime) to the Pt working electrode will result in an observed current that is proportional to the PO_2 present in the sample (including whole blood). In the absence of any oxygen, the current at this applied voltage under amperometric conditions will be very near zero.

The outer gas-permeable membrane enables the Clark electrode to detect oxygen with very high selectivity over

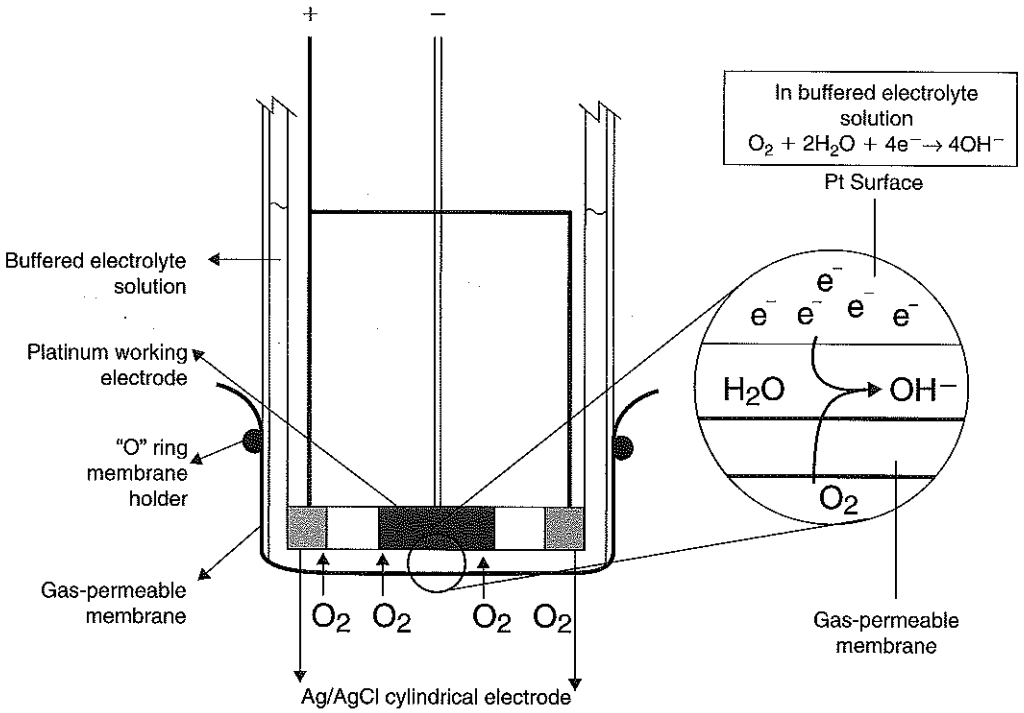

Figure 4-8 Design of Clark style amperometric oxygen sensor used to monitor PO_2 levels in blood.

other easily reduced species that might be present in a given sample (e.g., metal ions, cystine, etc.). Indeed, only other gas species or highly lipophilic organic species can partition into and pass through such gas-permeable membranes. One type of interference in clinical samples can be certain anesthesia gases, such as nitrous oxide, halothane, and isoflurane. These species can also diffuse through the outer membrane of the sensor, be electrochemically reduced at the platinum electrode, and yield a false positive value for the measurement of PO_2.[26] However, optimized gas-permeable membrane materials and appropriate control of the applied potential to the cathode of the sensor have greatly reduced this problem in modern instruments. The outer gas-permeable membranes also help restrict the diffusion of analyte to the inner working electrode; hence the membrane can control the mass transport of analyte (D/δ term in equation 16), such that in the presence or absence of sample convection, mass transport of oxygen to the surface of the platinum working electrode is essentially the same.

The basic design of the Clark amperometric PO_2 sensor can be extended to detect other gas species by altering the applied voltage to the working electrode. For example, it is possible to detect nitric oxide (NO) with high selectivity using a similar gas electrode design in which the platinum is polarized at +0.900 vs. Ag/AgCl to oxidize diffusing NO to nitrate at the platinum anode.[10] Such NO sensors can be used for a variety of biomedically important studies to deduce the amount of NO locally at or near the surface of various NO-producing cells.

Beyond amperometric devices, one specialized method for detecting trace levels of toxic metal ions in clinical samples is anodic stripping voltammetry (ASV). In ASV a carbon working electrode is used (sometimes further coated with a Hg film), and the E_{appl} is first fixed at a very negative E_{appl} voltage so that all metal ions in the solution will be reduced to elemental metals (M^0) within the mercury film and/or on the surface of the carbon. Then the E_{appl} is scanned more positive, and the reduced metals deposited in and/or on the surface of the working electrode are reoxidized, giving a large anodic current peak proportional to the concentration of metal ions in the original sample. The potential at which these peaks are observed indicates which metal is present, and the height of stripping peak current is directly proportional to the concentration of the metal ion in the original sample. Such ASV techniques can be used to detect the total concentration of Pb in whole blood samples, providing a rapid screening method for lead exposure and poisoning.[33]

Another biomedical example of modern voltammetry is a rapid scan cyclic voltammetric technique that has been used to quantify dopamine in brain tissue of freely moving animals.[78] In this application, oxidation of dopamine to a quinone species at an implanted microcarbon electrode (at approximately +0.600 V vs. Ag/AgCl) yields peak currents proportional to dopamine levels. The electrode can be used to measure this neurotransmitter in different regions of the brain or in a fixed location. Often, pharmacological or electrical stimulation can be employed to measure the

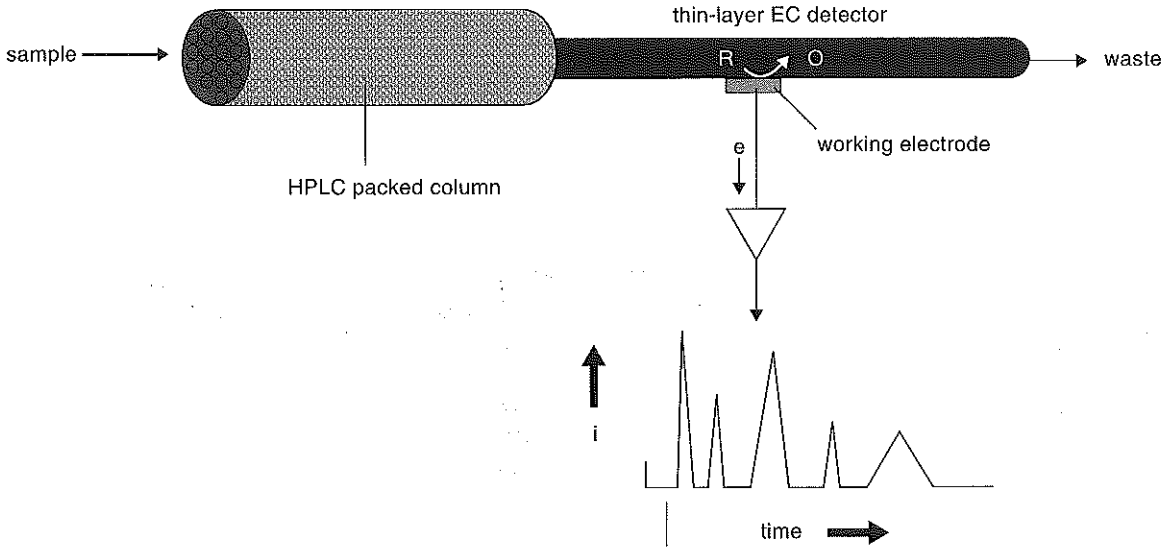

Figure 4-9 Schematic of LC-EC system, with electrochemical detector monitoring the elution of analytes from an HPLC column, by either their oxidation or reduction (shown here as example) at a suitable thin-layer working electrode.

change in local dopamine levels due to such stimulation techniques.

While voltammetric/amperometric techniques can be applied to detect a wide range of species, the selectivity offered for measurements in complex clinical samples—where many species can be electroactive—is rather limited. For example, as stated in the above discussion relevant to the Clark oxygen sensor, in the absence of the gas-permeable membrane, other species that can be reduced at or near the same E_{appl} as oxygen would cause significant interference.

To greatly expand the range of analytes that can be detected with voltammetric/amperometric methods, electrochemical techniques can be used as highly sensitive detectors for modern high performance liquid chromatographic (HPLC) systems (see Chapter 6). In liquid chromatography with electrochemical detection (LC-EC), eluting solutes are detected by flow-through electrodes (usually carbon or mercury) designed to have extremely low dead volumes (Figure 4-9). The electrodes can be operated in amperometric or voltammetric modes (with high scan speeds), and several electrodes can be operated simultaneously in series or in parallel flow arrangements to gain additional selectivity.[48] For example, homocysteine can be measured with (1) the addition of reducing agents to a serum sample to generate free homocysteine, (2) precipitation of proteins in the sample (with trichloroacetic acid), and (3) separation of the serum components on a reversed phase octadecylsilane HPLC column. The eluting homocysteine is detected and measured with online electrochemical detection via homocysteine oxidation to the corresponding mercuric dithiolate complex

$$2\,RSH + Hg \rightarrow Hg(RS)_2 + 2H^+ + 2e^- \qquad (22)$$

using a thin-layer Hg/Au amalgam electrode poised at +0.150 V vs. Ag/AgCl.[81] Integration of the eluting band for homocysteine provides quantitative results, with very high selectivity. Similarly, catechols and catecholamines can also be readily detected in serum by a similar LC-EC method, with the eluted catechols oxidized to quinones at a flow-through carbon working electrode poised at potentials typically >0.200 V vs. Ag/AgCl. Further, a host of therapeutic drugs can also be quantitated in serum or urine via LC-EC methods.

CONDUCTOMETRY

Conductometry is an electrochemical technique used to determine the quantity of an analyte present in a mixture by measurement of its effect on the electrical conductivity of the mixture. It is the measure of the ability of ions in solution to carry current under the influence of a potential difference. In a conductometric cell, potential is applied between two inert metal electrodes. An alternating potential with a frequency between 100 and 3000 Hz is used to prevent polarization of the electrodes. A decrease in solution resistance results in an increase in conductance and more current is passed between the electrodes. The resulting current flow is also alternating. The current is directly proportional to solution conductance. Conductance is considered the inverse of resistance and may be expressed in units of ohm^{-1} (siemens). In clinical analysis, conductometry is frequently used for the measurement of the volume fraction of erythrocytes in whole blood (hematocrit) and as the transduction mechanism for some biosensors.

Erythrocytes act as electrical insulators because of their lipid-based membrane composition. This phenomenon was first used in the 1940s to measure the volume fraction of erythrocytes in whole blood (hematocrit) by conductivity[80] and is used today to measure hematocrit on multianalyte instru-

ments for clinical analysis. The conductivity of whole blood depends not only on the volume fraction and shape of the erythrocytes but also on the conductivity of the surrounding plasma. An increase in the volume fraction of erythrocytes, that are less conductive than the surrounding plasma, leads to a decrease in conductivity shown by the following relationship[95]

$$G_b = \frac{a}{1} + \frac{H}{100-H} \times c \qquad (23)$$

where G_b is the conductivity of whole blood, a is the plasma conductivity, H is the percent of hematocrit and c is a factor for erythrocyte orientation. In practice, plasma conductivity also contains correction factors for Na^+ and K^+ concentrations. These cations are usually measured in conjunction with hematocrit on systems designed for clinical analysis.

Conductivity-based hematocrit measurements have limitations.[88] Abnormal protein levels will change plasma conductivity and interfere with the measurement. Low protein concentrations resulting from dilution of blood with protein-free electrolyte solutions during cardiopulmonary bypass surgery will result in erroneously low hematocrit values by conductivity. Preanalytical variables, such as insufficient mixing of the sample, will also lead to errors.[99] Hemoglobin is the preferred analyte to monitor blood loss and the need for transfusion during trauma and surgery. However, the electrochemical measurement of hematocrit in conjunction with blood gases and electrolytes remains in use mainly because of simplicity and convenience, despite some limitations.

Another clinical application of conductance is for electronic counting of blood cells in suspension. Termed the "Coulter principle," it relies on the fact that the conductivity of blood cells is lower than that of a salt solution used as a suspension medium.[21] The cell suspension is forced to flow through a tiny orifice. Two electrodes are placed on either side of the orifice, and a constant current is established between the electrodes. Each time a cell passes through the orifice, the resistance increases; this causes a spike in the electrical potential difference between the electrodes. The pulses are then amplified and counted.

COULOMETRY

Coulometry measures the electrical charge passing between two electrodes in an electrochemical cell. The amount of charge passing between the electrodes is directly proportional to oxidation or reduction of an electroactive substance at one of the electrodes. The number of coulombs transferred in this process is related to the absolute amount of electroactive substance by Faraday's Law:

$$Q = n \times N \times F \qquad (24)$$

where

Q = is the amount of charge passing through the cell (unit: C = coulomb = ampere · second)

n = the number of electrons transferred in the oxidation or reduction reaction

N = the amount of substance reduced or oxidized in moles

F = Faraday constant (96,487 coulombs/mole)

The measurement of current is related to charge as the amount of charge passed per unit time (ampere = coulomb/second). Coulometry is used in clinical applications for the determination of chloride in serum or plasma and as the mode of transduction in certain types of biosensors.

Commercial coulometric titrators have been developed for determination of chloride. A constant current is applied between a silver wire (anode) and a platinum wire (cathode). At the anode, Ag is oxidized to Ag^+. At the cathode, H^+ is reduced to hydrogen gas. At a constant applied current, the number of coulombs passed between the anode and cathode is directly proportional to time (coulombs = amperes × seconds). Therefore, the absolute number of silver ions produced at the anode may be calculated from the amount of time current passes through it. In the presence of Cl^-, Ag^+ ions formed are precipitated as $AgCl_{(s)}$ and the amount of free Ag^+ in solution is low. When all the Cl^- ions have been complexed, there is a sudden increase in the concentration of Ag^+ in solution. The excess Ag^+ is sensed amperometrically at a second Ag electrode, polarized at negative potential. The excess Ag^+ is reduced to Ag, producing a current. When this current exceeds a certain value, the titration is stopped. The absolute number of Cl^- ions present in the sample is calculated from the time during which the titration with Ag^+ was in progress. Knowing the volumetric amount of serum or plasma sample originally used, it is possible to calculate the concentration of Cl^- in the sample. Coulometric titration is one of the most accurate electrochemical techniques since the method measures the absolute amount of electroactive substance in the sample. Coulometry is considered the gold standard for determination of chloride in serum or plasma. However, the method is subject to interference from anions in the sample with affinity for Ag^+ greater than chloride, such as bromide.[97]

OPTICAL CHEMICAL SENSORS

An "optode" is an optical sensor used in analytical instruments to measure blood gases and electrolytes. Optodes have certain advantages over electrodes, including ease of miniaturization, less noise (no transduction wires), potential long-term stability using ratiometric type measurements at multiple wavelengths,[84] and no need for a separate reference electrode. These advantages promoted the development of optical sensor technology initially for design of intravascular blood gas sensors (see in vivo sensor section below). However, the same basic sensing principles can be used in clinical chemistry instrumentation designed for more classical in vitro measurements on discrete samples. In such systems, light can be brought to and from the sensing site either by optical fibers or simply by appropriate positioning of light sources (light emitting diodes, LEDs), filters, and

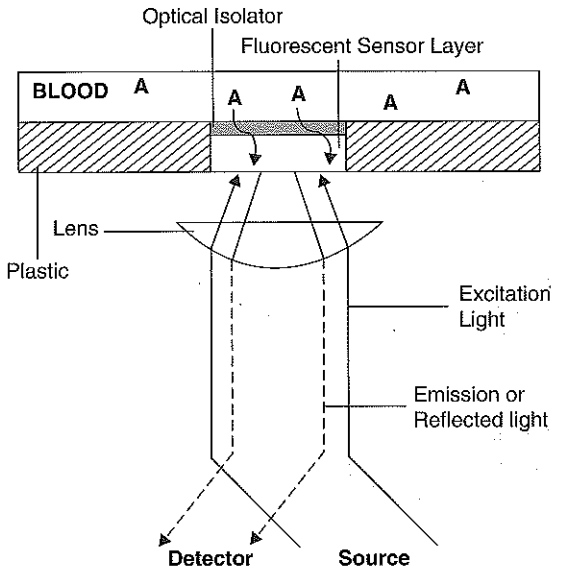

Figure 4-10 General design for in vitro optical sensor designed to detect given analyte in blood sample. Polymer film contains dye that changes spectral properties in proportion to the amount of analyte in the sample phase. Example shown is for sensing film that changes luminescence (fluorescence or phosphorescence).

photodetectors to monitor absorbance (by reflectance), fluorescence, or phosphorescence (Figure 4-10).

Basic Concepts

Optical sensors devised for PO_2 measurements are typically based on the immobilization of certain organic dyes (e.g., pyrene, diphenylphenanthrene, phenanthrene, fluoranthene, etc.) or metal ligand complexes (e.g., ruthenium[II] tris[dipyridine], Pt and Pd metalloporphyrins, etc.) within hydrophobic polymer films (e.g., silicone rubber) in which oxygen is very soluble.[25] The fluorescence or phosphorescence of such species at a given wavelength is often quenched in the presence of paramagnetic species, including molecular oxygen. In the case of embedded fluorescent dyes, the intensity of the emitted fluorescence of such films will decrease in proportion to the PO_2 level of the sample in contact with the polymer film, in accordance with the Stern-Volmer equation for quenching:

$$\frac{I_0}{I_{PO_2}} = 1 + kPO_2 \qquad (25)$$

where

I_0 = fluorescence intensity in the absence of any oxygen
I_{PO_2} = fluorescence intensity at a given PO_2 level
k = quenching constant for the particular fluorophore used

Hence a linear relationship exists between the ratio I_0/I_{PO_2} and the PO_2 in the sample phase. The larger the Stern-Volmer constant, the greater the degree of quenching for the given fluorophore. However, it is important that the quenching constant is in a range that will yield linear Stern-Volmer behavior over the physiologically relevant range of PO_2 in blood. For example, if k is too large, then maximum quenching possible will occur over a range of PO_2 that is less than physiological.

Phosphorescence intensity or phosphorescence lifetime measurements of immobilized metal ligand complexes can also be employed (i.e., binding of oxygen decreases excited state lifetimes). Sensors based on changes in luminescent lifetime have the inherent advantage of being insensitive to perturbations in the optical pathlength and the amount of active dye present in the sensing layer.

Optical pH sensors require immobilization of appropriate pH indicators (e.g., fluorescein, 8-hydroxy-1,2,6-pyrene trisulfonate [HPTS], phenol red, etc.) within thin layers of hydrophilic polymers (e.g., hydrogels), since equilibrium access of protons to the indicator is essential. The absorbance or fluorescence of the protonated or deprotonated form of the species can be used for sensing purposes.[84] One issue with respect to using immobilized indicators for accurate physiological pH measurements is the effect of ionic strength on the pKa of the indicator. Because optical sensors measure the concentration of protonated or deprotonated dye as an indirect measure of hydrogen ion activity, variations in the ionic strength of the physiological sample can influence the accuracy of the pH measurement.

Applications

Optical sensors suitable for the determination of PCO_2 employ optical pH transducers (with immobilized indicators) as inner transducers in an arrangement quite similar to the classical Severinghaus style electrochemical sensor design (see Figure 4-4). The addition of bicarbonate salt within the pH sensing hydrogel layer creates the required electrolyte film layer, which varies in pH depending on the level of PCO_2 in equilibrium with the film. The optical pH sensor is covered by an outer gas-permeable hydrophobic film (e.g., silicone rubber), to prevent proton access, yet allows CO_2 equilibration with the pH-sensing layer. As the PCO_2 level in the sample increases, the pH of the bicarbonate layer decreases, and the corresponding decrease in the concentration of the deprotonated form of the indicator (or increase in the concentration of protonated form) is sensed optically.

Two approaches have been used to sense electrolyte ions optically in physiological samples. One method employs many of the same lipophilic ionophores developed for polymer membrane type ion-selective electrodes (see Figure 4-3).[6,13] These species are doped into very thin hydrophobic polymeric films along with a lipophilic pH indicator. In the case of cation ionophores (e.g., valinomycin for sensing potassium), when cations from the sample are extracted by the ionophore into the thin film, the pH indicator (RH) loses a proton to the sample phase to maintain charge neutrality within the organic film (yielding R^-). This results in a change in the optical absorption or fluorescence spectrum of the polymer layer. If the thickness of the films is kept <10 μm,

equilibrium response times on the order of <1 min have been achieved. The main limitation of this design is that the pH of the sample phase also influences the overall extraction equilibrium for ions into the film. Thus either simultaneous and independent measurement of sample pH is required, or buffered dilution and/or pH control of the sample phase is necessary to obtain accurate measurements of electrolytes.

A second methodology used to sense electrolyte ions is to immobilize a cation and/or anion recognition agent within a hydrogel matrix, similar to the pH sensors described above. The recognition agent in this case is not usually lipophilic, and therefore it must be covalently anchored to the hydrogel so that it does not leach into the sample phase. The agent is designed so that selective cation or anion binding alters the absorbance or fluorescence spectrum of the species within the hydrogel. Typically, this is achieved by linking both ion recognition and chromophoric properties within a single organic molecule. Such ion sensors have been employed successfully in at least one commercial blood gas-electrolyte analyzer using an array of sensors of the generic design similar to that illustrated in Figure 4-10.

BIOSENSORS

A biosensor is a specific type of chemical sensor consisting of a biological recognition element and a physico-chemical transducer, often an electrochemical[45,90] or an optical device. The biological element is capable of recognizing the presence and activity and/or concentration of a specific analyte in solution. The recognition may be either a *biocatalytic reaction (enzyme-based biosensor)* or a *binding process (affinity-based biosensor)*, when the recognition element is, for example, an antibody, DNA segment, or cell receptor. The interaction of the recognition element with a target analyte results in a measurable change in a solution property locally at the surface of the device, such as formation of a product or consumption of a reactant. The transducer converts the change in solution property into a quantifiable electrical signal. The mode of transduction may be one of several, including electrochemical, optical, and the measurement of mass or heat. The present discussion will be limited to biosensors based on electrochemical and optical modes of transduction since they comprise the majority of biosensors used for clinical applications.

Enzyme-Based Biosensors with Amperometric Detection

Enzyme-based biosensors based on electrochemical transducers, specifically amperometric electrodes, are the most commonly used for clinical analyses and the most frequently cited in the literature.[44] Clark and Lyons developed the first amperometric biosensor; it was used for measuring glucose in blood and was based on immobilizing glucose oxidase on the surface of an amperometric PO_2 sensor.[18] A solution of glucose oxidase was physically entrapped between the gas-permeable membrane of the PO_2 electrode and an outer semipermeable membrane (see Figure 4-11 general design). The outer membrane was of a low molecular weight cut-off to allow substrate (glucose) and oxygen from the sample to pass, but not proteins and other macromolecules. In this way, enzymes could be concentrated at the sensor's surface. The oxidation of glucose, catalyzed by glucose oxidase

$$\text{Glucose} + O_2 \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + H_2O_2 \quad (26)$$

consumes oxygen near the surface of the sensor. The rate of decrease in PO_2 is a function of the glucose concentration and is monitored by the PO_2 electrode. A steady-state reduced level of oxygen can be achieved at the surface in a

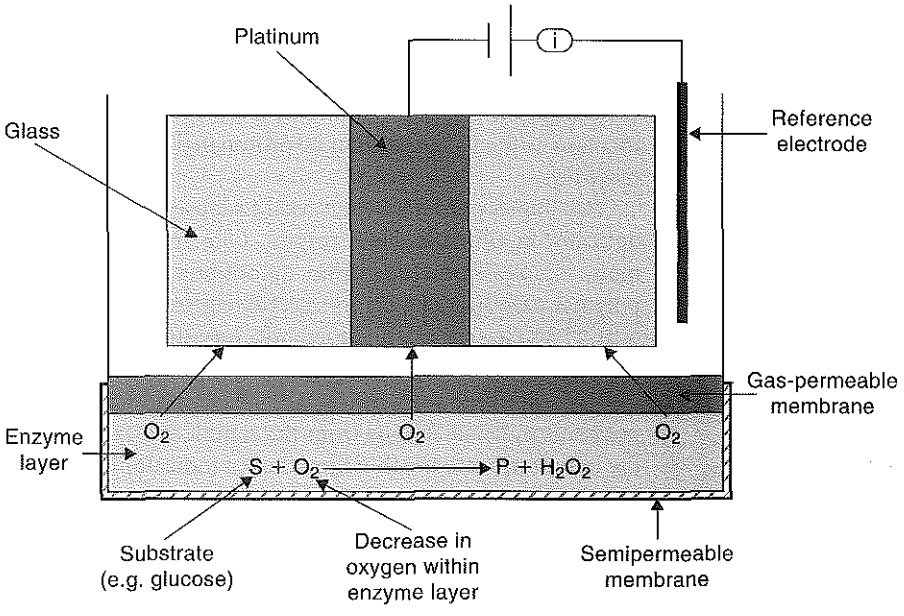

Figure 4-11 Illustration of enzyme electrode prepared using oxidase enzyme immobilized at the surface of amperometric PO_2 sensor. Increase in substrate concentration S reduces the amount of oxygen present at the surface of the sensor.

short period of time, yielding a steady-state current value that decreases as a function of glucose concentration in the sample.

If the polarizing voltage of the PO_2 electrode is reversed, making the platinum electrode positive (anode) relative to the Ag/AgCl reference electrode, and if the gas permeable membrane is replaced with a hydrophilic membrane containing the immobilized enzyme, it is possible to oxidize the H_2O_2 produced by the glucose oxidase:

$$H_2O_2 \rightarrow 2e^- + O_2 + 2H^+ \qquad (27)$$

The steady-state current produced is now directly proportional to the concentration of glucose in the sample.

In practice, a sufficiently high voltage (overpotential) must be applied to the platinum anode to drive the oxidation of the hydrogen peroxide. An applied voltage of +0.7 volts or greater (relative to Ag/AgCl) is typically used. Figure 4-12 illustrates this basic hydrogen peroxide detection design, which is suitable for use in devising clinically useful sensors for glucose, but also for a host of other substrates for which there are suitable oxidase enzymes that generate hydrogen peroxide.

Immobilization of enzymes in the early biosensors was a simple entrapment method behind a membrane of low molecular weight cut-off, and this approach is still used in some commercial applications. Many other schemes for enzyme immobilization for biosensor development have been suggested.[41] Most common are cross-linking of the enzyme with an inert protein, such as bovine serum albumin (BSA), using glutaraldehyde, simple adsorption of enzyme to electrode surfaces, or covalent binding of enzymes to insoluble carriers, such as nylon or glass. Another immobilization technique involves bulk modification of an electrode material, mixing enzymes with carbon paste, which serves as both the enzyme immobilization matrix and the electroactive surface.[38]

One of the first biosensor based systems for the measurement of glucose in blood was commercialized by Yellow Springs Instruments, Inc. (YSI), Yellow Springs, Ohio, in 1975 and used the amperometric detection of H_2O_2 as the measurement principle (see Figure 4-12). Dependence of the measured glucose value on the oxygen concentration in the sample was a problem since there is significantly less than the stoichiometric amount of dissolved oxygen in blood to support the glucose oxidase reaction and produce a linear relationship of signal with glucose concentration. This is especially true at high levels of glucose found in samples from diabetic patients (>500 mg/dL). In the case of the YSI system, the sample and calibration solutions are diluted at least 1:10 in buffer (depends on model), which is in equilibrium with atmospheric PO_2, fixing the oxygen concentration in the calibrator and sample at a constant level.

The problem of oxygen limitations of biosensors based on oxidase enzymes has been addressed by designing semipermeable membranes that restrict the diffusion of the primary analyte (substrate) to the enzyme layer, avoiding saturation of the enzyme, and keeping the ratio of oxygen to analyte always in excess of 1. This extends the linearity of response to analyte concentrations substantially higher than the K_m of the enzyme, and reduces the signal dependence on oxygen. Outer track-etched polycarbonate membranes are commonly used,[76] and membranes of poly (vinyl chloride), polyurethanes, and silicone emulsions.[60] Another approach has been to use an oxygen-rich electrode material as a reservoir of oxygen to support the bioreaction. A fluorocarbon (Kel-F oil) has been used to formulate a carbon paste electrode to act both as a source of oxygen and the working electrode.[96]

Electron acceptors other than oxygen can serve as mediators in the glucose oxidase reaction, and completely eliminate any dependence of the amperometric response on oxygen concentration of the sample. The mediator, usually co-immobilized with the enzyme, transports electrons to the

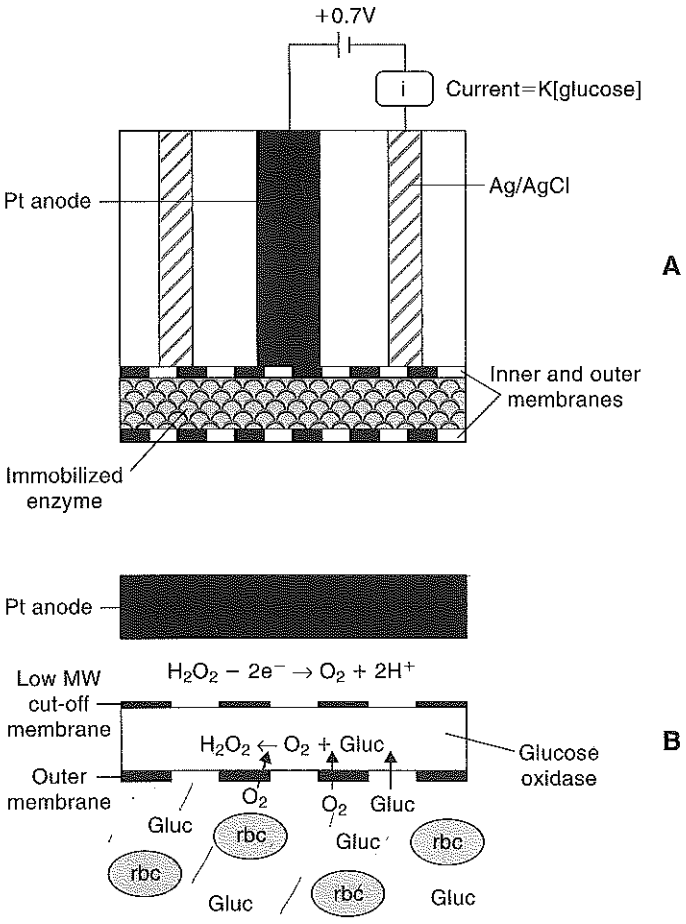

Figure 4-12 Design of amperometric enzyme electrode based on anodic detection of hydrogen peroxide generated from oxidase enzymatic reaction (e.g., glucose oxidase) **(A),** and expanded view of the sensing surface showing the different membranes and electrochemical process that yield the anodic current proportional to the substrate concentration in the sample **(B).** *(From Meyerhoff M, New in vitro analytical approaches for clinical chemistry measurements in critical care. Clin Chem 1990;36:1570.)*

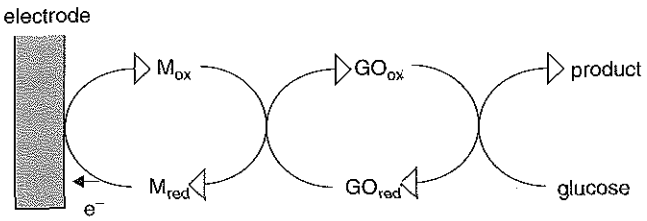

Figure 4-13 Scheme showing the use of electroactive mediator in the design of an amperometric enzyme electrode. The mediator accepts electrons directly from the enzyme, and is oxidized at the surface of the working electrode, creating more oxidized mediator to continue this process. *(From D'Orazio P. In: Lewendrowski, K, ed. Clinical chemistry laboratory management and clinical correlations, Philadelphia: Lippincott, Williams and Wilkins, 2002: 464.)*

anode surface, where it is reoxidized, resulting in a cyclic reaction mechanism (Figure 4-13). Mediators with electron transfer kinetics (little or no overpotential) more favorable than oxygen allow operation of the sensor at lower applied potentials (+0.2 V vs. Ag/AgCl or lower) than is typically used for the oxidation of H_2O_2. This approach not only eliminates dependency of the reaction rate on oxygen, but also serves to reduce the contribution from oxidizable interfering substances (e.g., uric acid, ascorbic acid, acetaminophen, etc.) on the sensor response. Examples of mediators that have been used include quinones and conductive organic salts, such as tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ).[35,74] Ferricyanide and ferrocene derivatives have also been employed,[15] including commercial application in a device for home blood glucose monitoring (ExacTECH™, Abbott-Medisense). In this device, dimethylferrocene is impregnated into a graphite electrode to which glucose oxidase has been immobilized. Reduced glucose oxidase from the enzymatic reaction is reoxidized by the electrochemically generated ferricinium ion. Current is produced during this cycling mechanism, which is proportional to the concentration of glucose in the blood sample.

Another technique to decrease interferences from easily oxidized species in a blood sample when using traditional H_2O_2 electrochemical detection is to employ selectively permeable membranes in proximity to the electrode surface that allow transport of H_2O_2 to the electrode surface, but reject the interfering substances based on size exclusion (see Figure 4-12, *B*). An example is as simple as a low molecular weight cut-off membrane, such as cellulose acetate, used in many commercial amperometric biosensors.[50] Also used are electropolymerized films, such as poly (phenylenediamine), formed in-situ, to reject interfering substances based on size.[30] Another approach employed in a commercial application involves using a second correcting electrode, identical to the working electrode, but without enzyme, sensitive only to the presence of oxidizable interfering substances. The resulting differential signal is proportional to the concentration of analyte.

A novel approach used for the elimination of electroactive interfering substances in a commercially available glucose sensor is to directly "wire" the redox center of the enzyme glucose oxidase to a metallic, amperometric electrode using an osmium (III/IV)-based redox hydrogel.[70] The osmium sites effectively serve as mediators, and can accept electrons directly from the entrapped enzyme, without need for oxygen. This approach allows the operating potential of the electrode to be dramatically lowered to +0.2 V vs. SCE (saturated calomel reference electrode), where currents resulting from electrooxidation of ascorbate, urate, acetaminophen, and L-cysteine are negligible.

Substitution of other oxoreductase enzymes for glucose oxidase allows amperometric biosensors for other substrates of clinical interest to be constructed. Practical sensors with commercial application in critical care analyzers for blood lactate have been realized.[1] Other amperometric biosensors reported include cholesterol, pyruvate, alanine, glutamate, and glutamine. By using the multiple enzyme cascade shown in the reactions below, an amperometric biosensor for creatinine is also possible. Electrochemical oxidation of H_2O_2 is the detection mechanism.

$$\text{Creatinine} + H_2O \xrightarrow{\text{creatinine amidohydrolase}} \text{Creatine} \quad (28)$$

$$\text{Creatine} + H_2O \xrightarrow{\text{creatine amidinohydrolase}} \text{Sarcosine} + \text{Urea} \quad (29)$$

$$\text{Sarcosine} + H_2O + O_2 \xrightarrow{\text{sarcosine oxidase}} \text{Glycine} + \text{formaldehyde} + H_2O_2 \quad (30)$$

This three-enzyme scheme suffers interference from endogenous creatine in the sample, requiring correction. Low concentrations of creatinine found in blood (≤100 μmol/L) must be measured in the presence of oxidizable interfering substances, sometimes present at higher concentrations than the analyte.[47] Special electroactive layers within the biosensor have been proposed to remove redox-active interfering substances.[85] Since the useful life of the creatinine biosensor based on these reactions requires three enzymes to retain activity, reusable commercial biosensors for creatinine based on this measurement principle typically suffer from a short useful life of only a few days.

Enzyme-Based Biosensors with Potentiometric and Conductometric Detection

Ion selective electrodes can also be used as transducers in potentiometric biosensors. An example is a biosensor for urea (blood urea nitrogen, BUN) based on a polymembrane ISE (vinyl chloride) for ammonium ion (Figure 4-14).[52] The enzyme urease is immobilized at the surface of the ammonium selective ISE based on the antibiotic nonactin (see structure of ionophore in Figure 4-3), and catalyzes the hydrolysis of urea to NH_3 and CO_2.

$$\text{Urea} \xrightarrow{\text{urease}} 2NH_3 + CO_2 \quad (31)$$

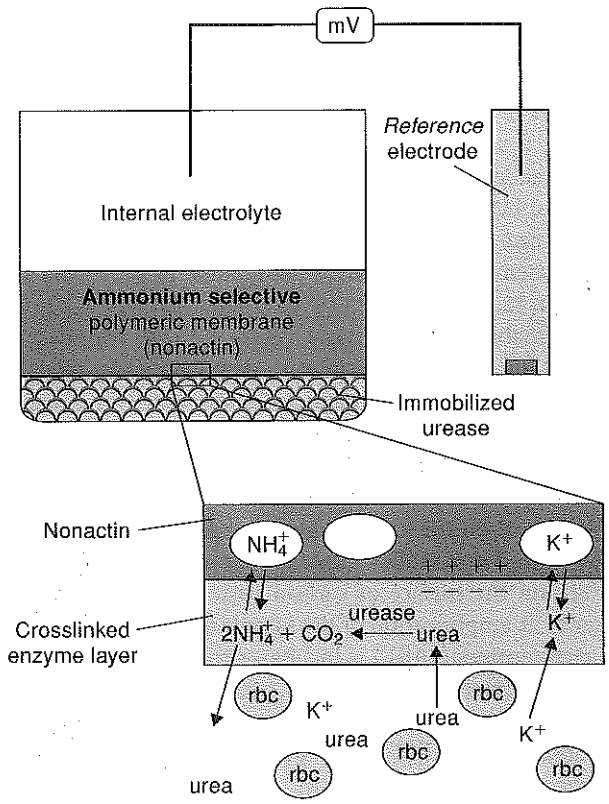

Figure 4-14 Potentiometric enzyme electrode for determination of blood urea, based on urease enzyme immobilized on the surface of an ammonium ion–selective polymeric membrane electrode.

The ammonia produced dissolves to form NH_4^+, which is sensed by the ISE. The signal generated by the NH_4^+ produced is proportional to the logarithm of the concentration of urea in the sample. The response may be either steady state or transient. Typically, correction for background potassium is required, since the nonactin ionophore has limited selectivity for ammonium over potassium ($K_{NH4/K} = 0.1$). Potassium is measured simultaneously with urea and used to correct the output of the urea sensor using the Nicolsky-Eisenman equation.

The above approach for measurement of urea using an enzyme-based potentiometric biosensor assumes that the turnover of urea to ammonium at steady state provides a constant ratio of ammonium ions to urea, independent of concentration. This is rarely the case, especially at higher substrate concentrations, resulting in a nonlinear sensor response. The linearity of the sensor is also limited by the fact that hydrolysis of urea produces a local alkaline pH in the vicinity of the ammonium-sensing membrane, partially converting NH_4^+ to NH_3 (pKa = 9.3). Ammonia (NH_3) is not sensed by the ISE. The degree of nonlinearity may be reduced by placement of a semipermeable membrane between enzyme and sample to restrict diffusion of urea to the immobilized enzyme layer.

A change in solution conductivity has also been used as a transduction mechanism in enzyme-based biosensors. Examples include the measurement of glucose, creatinine, and acetaminophen using interdigitated electrodes.[23] Practical applications of conductometric biosensors are few because of the variable ionic background of clinical samples and the requirement to measure small conductivity changes in media of high ionic strength. A commercial system for the measurement of urea in serum, plasma, and urine is a BUN analyzer (Beckman-Coulter) based on the enzyme urease.[27] Dissolution of the products to NH_4^+ and HCO_3^- produces a change in sample conductivity. The initial rate of change in conductivity is measured to compensate for the background conductivity of the sample. This approach is limited to the measurement of analytes at relatively high concentrations because of small changes in conductivity produced by low levels of analyte.

Enzyme-Based Biosensors with Optical Detection

Optical sensors with immobilized enzymes and indicator dyes have been developed for the measurement of glucose and other substrates of clinical interest.[54] These biosensors are based on optical detection chemistries for pH and oxygen, described earlier in this chapter, and rely on absorbance/reflectance, fluorescence, and luminescence as modes of detection. Enzyme immobilization methods resemble those used to construct electrochemical biosensors, including physical entrapment or encapsulation in a gel matrix, physical adsorption onto substrates, and covalent binding or absorption on an insoluble support. Using an example based on an optode for PO_2, a sensitive indicator is co-immobilized with an oxidase enzyme at the end of a fiber optic probe. The probe is used to monitor fluorescence of the indicator. Quenching of fluorescence of the indicator by O_2 is followed. A decrease in PO_2 resulting from a reaction catalyzed by the enzyme will result in less quenching of the indicator and a fluorescent signal directly proportional to the concentration of substrate. In an example of an optical biosensor probe for glucose, an oxygen, sensitive cationic dye, $Ru(phen)_3^{2+}$, is immobilized along with glucose oxidase on the surface of an optical fiber.[67] A decrease in PO_2 arising from the enzyme-catalyzed oxidation of glucose results in an increase in luminescence intensity of the ruthenium tris(phenanthrene).

Similar optical biosensors have been prepared for many other analytes. For example, a cholesterol optical biosensor has been devised based on fluorescence quenching of an oxygen-sensitive dye that is coupled to consumption of oxygen resulting from the enzyme-catalyzed oxidation of cholesterol by the enzyme cholesterol oxidase.[93] Serum bilirubin has been detected using bilirubin oxidase, co-immobilized with a ruthenium dye, on an optical fiber.[56] The bilirubin sensor was reported to exhibit a lower detection limit of 10 μmol/L, a linear range up to 30 mmol/L, and a typical reproducibility of 3% (CV), certainly adequate for clinical application.

The pH change resulting from enzyme-catalyzed reactions has also been measured optically. The indicator dye fluorescein is often used as a pH-sensitive indicator to construct such sensors. The protonated form of fluorescein does not fluoresce, but the conjugate base strongly fluoresces at 530 nm, when excited at 490 nm. Using glucose oxidase as the enzyme, a pH optode has been employed to follow the formation of gluconic acid.[92] A disadvantage of optical sensors based on pH changes is that they are strongly dependent on the pH and buffer capacity of the sample. Moreover, the working range of the sensor is determined by the pKa of the indicator, 6.8 to 7.2 for fluorescein, depending on ionic strength of the sample matrix. A pH-sensitive indicator may also be used to follow enzymatic reactions producing ammonia (e.g., urease action on urea).

Affinity Sensors

Affinity sensors are a special class of biosensors in which the immobilized biological recognition element is a binding protein, antibody (immunosensors), or oligonucleotide (e.g., DNA, aptamers, etc.) with high binding affinity and high specificity toward a clinically important analyte/partner. Such sensors are being developed as alternatives to conventional binding assays to enhance the speed and convenience of a wide range of assays that would be normally run on sophisticated instruments (e.g., immunoassay analyzers, etc.). Ideally, direct binding of the immobilized species with its target in a clinical sample should yield a sensor signal proportional to the concentration of the analyte. However, "direct" sensing (without use of exogenous labels/tracers) of the binding events at analyte concentrations that would cover the full range for clinical applications is very difficult to achieve. Further, high affinity of such binding reactions, required to achieve optimal sensitivity, also limits the reversibility of such devices (slow reverse rate constant). Indeed, unlike ISEs, oxygen sensors, and many of the enzyme type biosensors described above, affinity sensors based on electrochemical, optical, or other transduction modes are typically single-use devices.[31] For repeated multiuse applications, some type of regeneration step (pH change, etc.) to dissociate the tight binding between the recognition element and target is required.[57]

A host of "direct" sensing affinity sensors have been proposed, based on either electrochemical (including capacitance changes), optical, thermal, mass, and acoustic detection methods.[46,57,62,87] Of these, few have adequate specificity to be used in complex clinical samples, owing to significant signals arising from nonspecific binding. One report, however, suggests that alpha fetoprotein can be detected reliably in serum samples via a quartz crystal microbalance type mass detector, possessing immobilized antialpha-fetoprotein antibodies on the surface of the quartz crystal transducer.[17] Increasing concentrations of analyte in the sample yield increased binding to the surface, changing the mass loaded because of the immunological reaction. Incubation times as low as 20 min are required to achieve results that compare favorably to a conventional radioimmunoassay method for serum samples.

Some success for direct sensing devices has also been achieved in the area of DNA sensors.[46] Generally, in such devices, a segment of DNA complementary to the target strand is immobilized on a suitable transducer. Electrochemical DNA sensors have received considerable attention in this regard, since they can operate in the direct (based on electrochemical oxidation of guanine in target DNA) (see Figure 4-15, *A*) or indirect (with exogenous electrochemical markers/labels, see below and Figure 4-15, *B*) transduction modes. For example, Ozkan et al. demonstrated a relatively simple label-free electrochemical "genosensor" for detecting the presence of factor V Leiden mutations, using capture probes with inosine substituted for guanosine nucleic acids.[73] Probes were developed to bind wild-type and mutant DNA, based on the known base sequences in the regions of the wild and mutant DNA species. These probes were immobilized on the surface of carbon paste working electrodes. After PCR amplification of the sample DNA, a small volume of such samples (10 μL) is incubated for 6 minutes with the probe-modified electrode. Then, after a quick washing step, the presence of the target amplicon bound to the surface can be observed by differential pulse voltammetry using an anodic scan. The presence of a guanine oxidation peak, occurring at +1.00 V vs. Ag/AgCl reference, indicates the presence of the target DNA in the original sample.

Most affinity type sensors that function well for real clinical measurements are usually based on labeled reagents such as enzymes, fluorophores, and electrochemical tags, and hence function more like traditional binding/immunoassays, except that one recognition element is immobilized on the surface of a suitable electrode or other type of transducer.[57,62,87] For example, electrochemical oxygen sensors have been employed to carry out heterogeneous enzyme immunoassays (sandwich or competitive type), using catalase as a labeling enzyme (catalyzes $H_2O_2 \rightarrow 2\,H^+$ and O_2), and immobilizing capture antibodies on the outer surface of the gas-permeable membrane. After binding equilibration and washing steps, the amount of bound enzyme is detected by adding the substrate and following the increase in current generation, owing to local production of oxygen near the surface of the sensor. Similar, heterogeneous enzyme immunoassays have been developed based on electrode detection of peroxide using oxidase enzyme labels, pH changes using urease as an enzyme label, etc.

DNA detection using electrochemical labeled oligonucleotides, or electrochemical probes that selectively intercalate into hybridized DNA duplexes, represents a growing area of investigation, with several "gene" sensor arrays of this type poised to become commercial products (see Chapter 37). As illustrated in Figure 4-15, *B*, when not using the intrinsic electroactivity of guanine (that requires use of electrode immobilized capture oligo probes with inosine replacing guanosine, see above), detection of hybridization of a target DNA sequence is achieved in either of two ways. In one case,

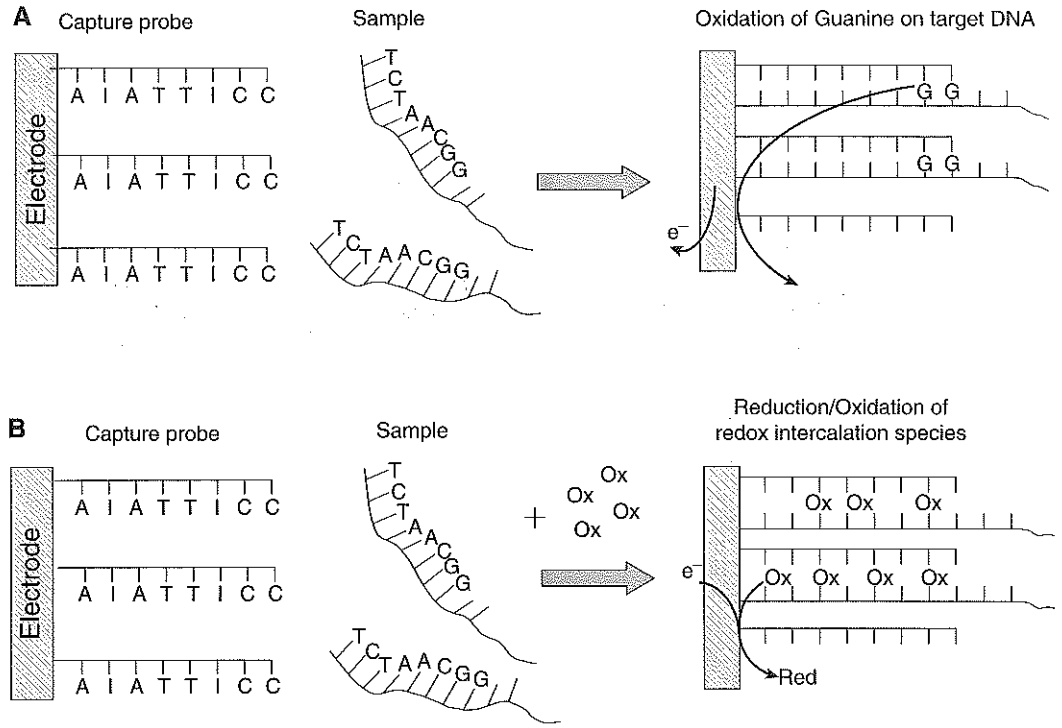

Figure 4-15 Examples of DNA biosensor configurations: **(A)** direct electrooxidation detection of guanosine bases in target DNA after hybridization with immobilized capture probe on electrode surface; **(B)** electrochemical detection of hybridization using exogenous redox species that intercalates into hybridized complex between immobilized capture DNA probe and target DNA.

after allowing the immobilized capture oligo anchored to the electrode surface to bind the target sequence, hybridization is detected by exposing the surface of the electrode to an exogenous electroactive species (Co(III)tris-phenanthroline, ruthenium complexes, etc.) that can interact (intercalate) with the duplex, but not single-stranded DNA. After washing away unbound electroactive species, the presence of hybridization can be readily detected by voltammetry, scanning the potential of the underlying electrode to oxidize or reduce any intercalated electroactive species, with the level of current detected being proportional to the number of duplex DNA species on the surface of the electrode.

A second route involves the detection of target DNA via a sandwich type binding assay, using an electrochemical-labeled oligonucleotide (oligo labeled with ferrocene, osmium(III) trisbipyridine, etc. to bind to another sequence of the targeted DNA different than the capture oligo on the surface of the electrode). Sequential exposure of the electrode to the sample of DNA (usually after amplification via PCR), excess of the labeled reporter oligo, a wash solution, and then electrochemical detection of surface bound label yields the analytical signal. Again, the amount of current monitored is proportional to the number of target DNA species present in the original sample.

The basic advantage of immobilizing affinity reagents on the surface of electrodes and optical sensing devices is somewhat diminished when separate washing steps are required to remove unbound label species. Indeed, true biosensors should yield analytically useful responses in the presence of undiluted physiological samples, without need for discrete incubation and washing steps. One example of an electrochemical-based immunosensor method that partly achieves this goal is a technique termed NEEIA (nonseparation electrochemical enzyme immunoassay).[64] The basic concept is illustrated in Figure 4-16. As indicated, no separation or washing steps are required. The method was used to detect prostate specific antigen (PSA) and hCG at ng/mL levels in undiluted plasma and whole blood.[64]

IN VIVO AND MINIMALLY INVASIVE SENSORS

Progress has been made in the development of miniaturized, implantable electrochemical/optical sensors that can be employed for in vivo, real-time monitoring of clinically important species. Unfortunately, the biological response of the living system toward such sensors (e.g., clotting, etc.) can have a dramatic impact on the analytical accuracy of such indwelling probes,[5,43,59,65] and has thus far prevented their widespread use in clinical practice. Progress is being made, however, to improve the reliability of in vivo measurements, and some commercial products are already on the market for in vivo blood gas and glucose monitoring.

Analytical sensors that can be implanted within human blood vessels or subcutaneously mandate that such sensing

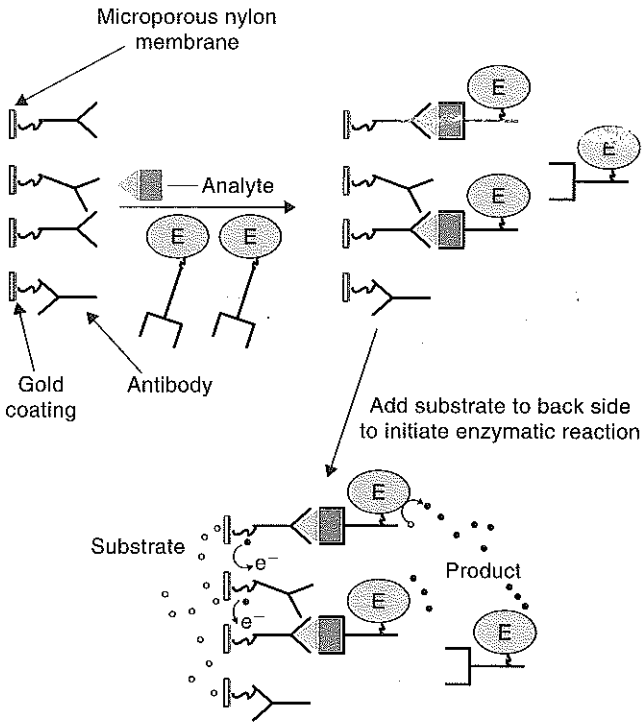

Figure 4-16 Principle of nonseparation electrochemical enzyme immunoassay (NEEIA) concept, configured in sandwich immunoassay mode to detect a given protein analyte. Enzyme label on reporter antibody generates an electroactive product that is detected at surface of porous gold electrode when substrate for enzyme is added to the back side of membrane.

devices have an outside diameter of <0.6 mm. Both electrochemical and optical sensor technologies have been employed to create devices having the required size. These are basically miniaturized versions of the electrochemical and optical sensor devices described above. However, in addition to small size, such devices must exhibit very stable output signals, since reliable calibration of the probes with calibrating solutions is not possible once the probes are inserted in vivo. While so-called in-situ calibration is possible (periodically removing in vitro blood sample to obtain current value of analyte, and update in vivo sensor output to this value), if the frequency of such in situ calibrations is high, the true advantage of having an in vivo probe is greatly diminished.

Continuous in vivo measurement of oxygen saturation (SaO_2) has been achieved with small optical fibers placed into the blood stream via a catheter and then measuring the reflective absorbance of the blood at two or three appropriately selected wavelengths that are based on the absorbance spectra of oxy- and deoxy-Hb.[19] In addition, implantable analytical sensors that provide continuous readings of blood gases (pH/PCO_2/PO_2) when inserted within the radial artery, especially for critically ill patients already fitted with an arterial line, are being developed.[79] Such sensors are usually based on the classical Clark style design in which oxygen is reduced at a microplatinum, silver, or gold working electrode confined (along with Ag/AgCl reference) within a narrow-diameter gas-permeable catheter tube made of a given polymer (see Figure 4-17, *A*), with the resulting current being proportional to the partial pressure of oxygen in the medium surrounding the catheter. Indwelling electrochemical pH and PCO_2 sensors are typically potentiometric devices, based on either polymer membrane pH electrode technology or use of solid-state metal oxide–based pH sensors. Incorporation of lipophilic proton ionophores (e.g., tridodecylamine; see Figure 4-3) within the walls of plastic tubing provides a convenient means to prepare a novel dual-lumen pH/PCO_2 sensing design that has been demonstrated to provide accurate in vivo results in animal experiments.[89]

Miniaturization of electrode designs that enable several sensors to be bundled into a single implantable device, however, remains a significant engineering challenge. Consequently, many of the efforts aimed at developing commercially viable intravascular blood gas sensors for monitoring pH, PCO_2 and PO_2 simultaneously have employed modern optical fiber–based technology alone or in combination with a single electrochemical device. As the outer diameter of available fibers continues to decrease, it is now possible to bundle three or more separate chemically sensitive fibers in a single catheter with an outer diameter <600 μm for implantation within human radial arteries, without dampening the pressure waveform detected by a microelectronic pressure transducer within the arterial line. Absorbance-, fluorescence-, and phosphorescence-based chemistries have all been investigated in the design of sensors with suitable selectivity and calibration stability.[65] Appropriate indicators are usually immobilized on the distal ends of the fibers, although alternate configurations/locations have also been proposed. Most optical oxygen measurements are made with indicators whose luminescence is quenched in the presence of oxygen, whereas pH sensors are prepared by immobilizing pH indicators (e.g., phenol red) in hydrogel type films.[84] Optical sensors for PCO_2 can be easily prepared from the same pH sensors by incorporating bicarbonate salt in the hydrogel layer and then covering this layer with a gas-permeable polymeric film (usually silicone rubber material), as described above in the section on optical sensors.

The Paratrend™ probe is commercially available and is used for the intravascular measurement of blood gases. It was originally developed by Pfizer/Biomedical Sensors and is currently distributed by Diametrics Inc. As shown in Figure 4-17, *B*, this indwelling sensor consists of a novel hybrid design, in which oxygen is sensed electrochemically (catheter form of Clark sensor) while pH and PCO_2 are determined via fiber-based optical fluorescence sensors.[94] While acceptable clinical performance of the Paratrend has been reported, frequent in situ recalibrations have been suggested.[20] A newer version of this product replaces the electrochemical oxygen sensor with an optical fiber design.

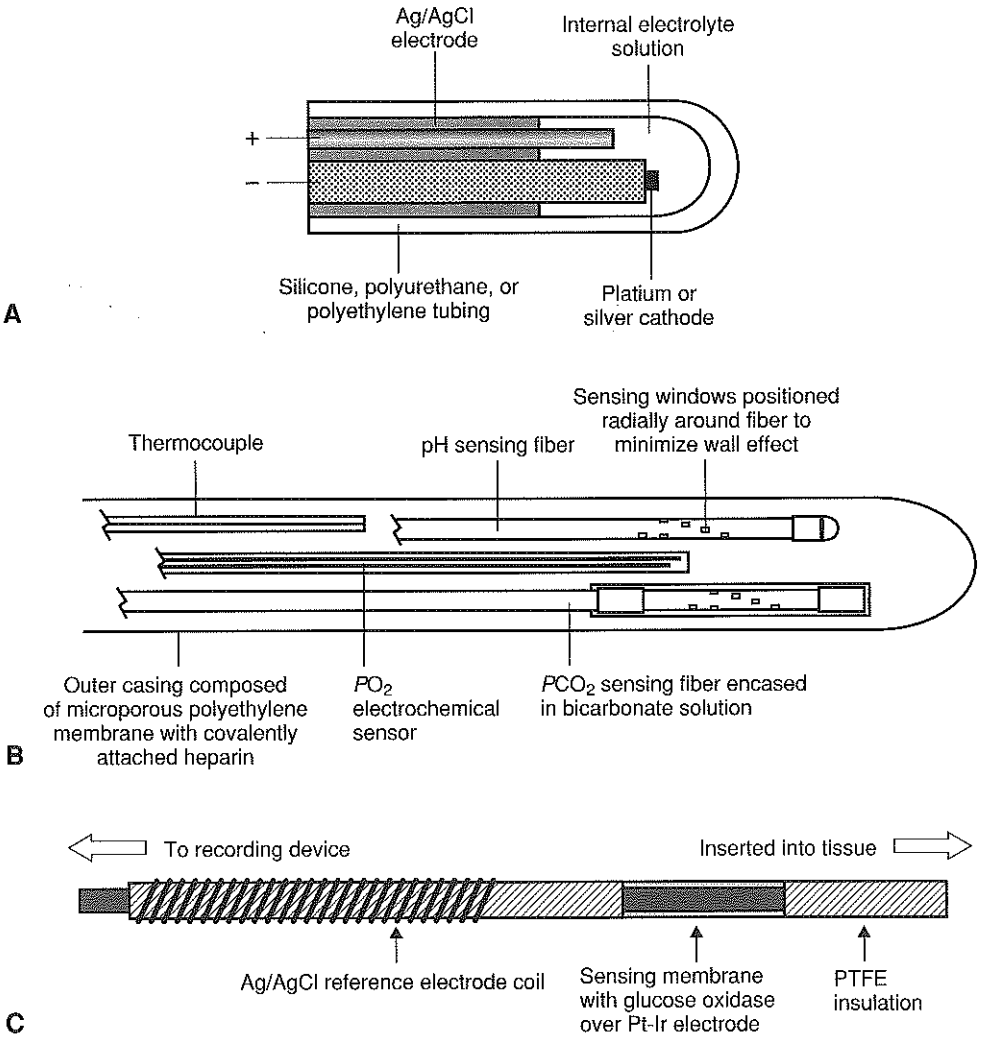

Figure 4-17 Schematics of various implantable electrochemical/optical sensors useful for continuous in vivo monitoring: **(A)** catheter style amperometric oxygen sensor; **(B)** design of Paratrend intravascular combined PO_2, PCO_2, and pH sensor (hybrid electrochemical/optical design); **(C)** needle type electrochemical glucose sensor useful for monitoring glucose subcutaneously to track blood glucose levels continuously.

Another class of in vivo chemical sensor that is now available are glucose sensors designed to help manage diabetic patients, with the ultimate goal of fully automated feedback control of subcutaneous insulin delivery via newly devised, highly portable insulin pumps. Since such sensors need to function within patients outside the hospital setting, and for extended time periods (days, weeks), placement of such devices subcutaneously, rather than intravascularly, is desirable.[49] In addition, sensors are being developed that could be implanted within the vena cava for periods of 1 year. In the case of subcutaneous devices, several studies have now shown that the levels of glucose in interstitial fluid track blood concentrations closely, although there is some time delay in achieving identical values in the two sample environments.[37]

Implantable glucose (and lactate) sensors have been based, almost exclusively, on electrochemical transducers. For example, one such sensor is based on using dual oxygen sensors in a single catheter design for indwelling blood glucose and lactate measurements.[39] One oxygen sensor with immobilized glucose or lactate oxidase provides response to glucose levels (decreasing surface oxygen levels in response to increase in glucose or lactate) while the second matched oxygen sensor, without enzyme, is able to correct for unknown and varying levels of endogenous PO_2. Others have focused on the design of probes with amperometric detection of the hydrogen peroxide (via oxidation) at an underlying iridium/platinum anode similar in operation to those used in vitro in commercial instruments.[98] In such designs, use of outer polymer films to restrict glucose (or lactate) diffusion relative to oxygen is critical to achieve linear electrochemical response to glucose from normal (90 mg/dL) to elevated levels found in diabetic patients (>500 mg/dL). Figure 4-17, *C* illustrates a design in which the

needle type probe is constructed by multiple membrane coatings and electrodeposition of the glucose oxidase layer.[16] A design quite similar to this is the only currently FDA-approved sensor that is available for subcutaneous monitoring of glucose.[40] The sensor is actually fabricated on a very narrow planar substrate, rather than on a cylindrical wire–based system. Relatively frequent calibration of the sensor is required via periodic in vitro blood tests, and after explantation, and hence the output of the device is not readable by the patient at this time.

Instead of implanting glucose sensors intravascularly or subcutaneously, an alternative approach employs electrochemical glucose sensors to monitor glucose levels in interstitial fluid brought to the surface of the sensors via an iontophoresis process.[91] Electrical current is passed through the skin to move fluid in a given direction toward the surface of the electrochemical glucose sensors that are based on peroxide detection (see Chapter 25 for additional discussion of this device.)

Current research and development efforts have focused on the use of more biocompatible coatings to reduce the biological response of both intravascular and subcutaneous devices. These efforts are based on the expectation that such developments will be critical to the ultimate success in developing implanted sensors that yield continuous analytical results that match closely with conventional in vitro test methods. One new approach in this direction employs novel nitric oxide (NO) release polymers to coat the surface of intravascular sensors.[36] The potent antiplatelet activity of NO has been shown to greatly reduce the formation of thrombus on the surface of implantable electrochemical oxygen sensing catheters, and yield much more accurate continuous PO_2 values in animal experiments.

CHAPTER 5

Electrophoresis*

Raymond Karcher, Ph.D.,
and James P. Landers, Ph.D.

Developments in deoxyribonucleic acid (DNA) testing, improvements in ease of performance through automation, and advantages of speed and miniaturization afforded by the technique of *capillary electrophoresis* (CE) have led to a renaissance and growth of *electrophoresis* as an analytical tool that is widely used in clinical laboratories. These developments and improvements have enabled clinical laboratories to keep pace with higher volumes of testing and introduce more sophisticated technology to meet the demands of modern clinical practice. This chapter will review the principles and practice of the technique and separately discuss conventional, capillary, and microchip electrophoresis. Particular attention is given to newer methods and their promise in fields such as *genomics* and *proteomics.*

BASIC CONCEPTS AND DEFINITIONS

Electrophoresis is a comprehensive term that refers to the migration of charged solutes or particles of any size in a liquid medium under the influence of an electrical field. *Iontophoresis* and *isotachophoresis (ITP)* are similar terms but refer specifically to the migration of small ions. The first electrophoresis method used to study proteins was the free solution or moving boundary method devised by Tiselius in 1937. The Tiselius apparatus was a rectangular, sectional U-tube equipped with sensitive Schlieren optics. It allowed changes in refractive index to be observed as segments of solution with different protein content migrated past. This technique was used in research to measure electrophoretic mobility and to study protein-protein interaction. It was able to resolve the serum proteins into only four component mixtures, with the α_1 fraction incompletely separated from albumin.

Zone electrophoresis refers to the migration of charged molecules, usually in a porous supporting medium like agarose gel film, such that each protein zone is sharply separated from neighboring zones by a protein-free area. Zones are visualized by staining with a protein-specific stain to produce an *electropherogram* that is then scanned and quantified using a densitometer. The support medium can also be handled after drying and kept as a permanent record. This is the most commonly applied technique in clinical chemistry and is used to separate proteins in serum, urine, cerebrospinal fluid (CSF), other physiological fluids, erythrocytes and tissue, and nucleic acids in various tissue cells.

THEORY OF ELECTROPHORESIS

Depending on the kind of charge they carry, ionized solutes move toward either the cathode (negative electrode) or the anode (positive electrode) in an electrophoresis system. For example, positive ions (cations) migrate to the cathode and negative ions (anions) to the anode. An ampholyte (a molecule that is either positively or negatively charged, formerly called a zwitterion) becomes positively charged in a solution more acidic than its isoelectric point (pI)* and migrates toward the cathode. In a more alkaline solution, the ampholyte becomes negatively charged and migrates toward the anode. Because proteins contain many ionizable amino (—NH_2) and carboxyl (—COOH) groups, and the bases in nucleic acids may also be positively or negatively charged, they both behave as ampholytes in solution.

*The authors gratefully acknowledge the original contributions of Drs. Emmanuel Epstein and Kern L. Nuttall on which portions of this chapter are based.

*The isoelectric point of a molecule is the pH at which it has no net charge and will not move in an electrical field.

The rate of migration of ions in an electrical field depends on factors such as the (1) net charge of the molecule, (2) size and shape of the molecule, (3) strength of the electric field, (4) properties of the supporting medium, and (5) temperature of operation. The equation expressing the driving force in such a system is given by

$$F = (X)(Q) = \frac{(\text{EMF})(Q)}{d} \quad (1)$$

where

F = the force exerted on an ion
X = the current field strength (V/cm) (i.e., voltage drop per unit length of medium)
Q = the net charge on the ion
EMF = the electromotive force (voltage [V] applied)
d = the length of the electrophoretic medium (cm)

The steady acceleration of the migrating ion is counteracted by a resisting force characteristic of the solution in which migration occurs. This force, expressed by Stokes' law, is

$$F' = 6\pi r\eta v \quad (2)$$

where

F' = the counter force
r = the ionic radius of the solute
η = the viscosity of the buffer solution in which migration is occurring
π = 3.1416
v = the rate of migration of the solute = velocity, length (l) traveled per unit of time (cm/s)

The force F' counteracts the acceleration that would be produced by F if no counter force were present, and the result of the two forces is a constant velocity. Therefore when

$$F = F' \quad (3)$$

then

$$6\pi r\eta v = (X)(Q) \quad (4)$$

or

$$\frac{v}{X} = \frac{l \times d}{t \times E} = \frac{Q}{6\pi r\eta} = \mu \quad (5)$$

where v/X is the rate of migration (cm/s) per unit field strength (E/cm), defined as the electrophoretic mobility. It is expressed by the symbol μ and has the units $cm^2/(V)(s)$.

The electrophoretic mobility is directly proportional to the net charge and inversely proportional to the size of the molecule and the viscosity of the electrophoresis medium. In practice the equation $\mu = cm^2/(V)(s)$ is used to calculate the electrophoretic mobility. Thus if albumin travels 3 cm (l) on a 10-cm (d) long agarose gel and does so in 75 minutes (or 75×60 s) at a voltage of 250 V, then

$$\mu = \frac{(3)(10)}{(75)(60)(250)} = 2.7 \times 10^{-5}\ cm^2/(V)(s)$$

Since one mobility unit is defined as $10^{-5}\ cm^2/(V)(s)$, this result is converted to 2.7 mobility units. Mobility may be positive or negative, depending on whether a protein migrates in the same or the opposite direction as the electrophoretic field (defined as extending from the anode to the cathode). In the example just given, electrophoresis was performed at pH 8.6 where proteins have a negative charge; therefore migration occurred from the cathode to the anode, and the mobility would be −2.7 mobility units.

Another factor and potential problem that can affect mobility is *wick flow*. During electrophoresis heat evolved because of the passage of current through a resistive medium can cause evaporation of solvent from the electrophoretic support. This drying effect draws buffer into the support from both buffer compartments. If significant, the flow of buffer from both directions can affect protein migration and hence the calculated mobility.

CONVENTIONAL ELECTROPHORESIS

In this section, instrumentation, general electrophoretic operations, technical and practical considerations, and types of conventional electrophoresis are discussed.

INSTRUMENTATION

Although modern electrophoresis equipment and systems vary considerably in form and degree of automation, the essential components common to all systems (Figure 5-1) include two reservoirs (1), which contain the buffer used in the process a means of delivering current from a power supply via platinum or carbon electrodes (2), which contact the buffer, and a support medium (3) in which separation takes place connecting the two reservoirs. In some systems, wicks (4) may connect the medium to the buffer solution or directly to the electrodes. The entire apparatus is enclosed (5) to minimize evaporation and protect both the system and the operator. The direct current power supply sets the polarity of the electrodes and delivers current to the medium.

Power Supplies

The power supply drives the movement of ionic species in the medium and allows adjustment and control of either the current or the voltage. In more sophisticated units, the power may be controlled as well and conditions may be programmed to change during electrophoresis. Capillary systems use power supplies capable of providing voltages in the kilovolt range.

Current flowing through a resistive medium produces heat:

$$\text{Heat} = (E)(I)(t) \quad (6)$$

where

E = EMF in volts (V)
I = current in amperes (A)
t = time in seconds (s)

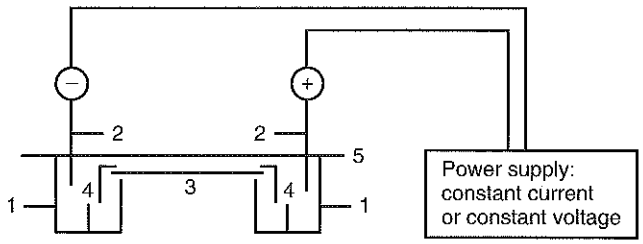

Figure 5-1 A schematic diagram of a typical electrophoresis apparatus showing two buffer boxes with baffle plates (*1*), electrodes (*2*), electrophoretic support (*3*), wicks (*4*), cover (*5*), and power supply.

This heat is released into the medium and increases the thermal agitation of all dissolved ions, and therefore the conductance of the system (decreases the resistance). With constant-voltage power supplies, the resultant rise in current increases both protein migration and evaporation of water from the medium. Any water loss increases the ion concentration and further decreases the resistance (R). Under these circumstances, the current and therefore the migration rate will progressively increase. To minimize these effects, it is best to use a constant-current power supply. According to Ohm's law:

$$E = (I)(R) \tag{7}$$

Therefore if R decreases, the applied EMF also decreases, keeping the current constant. This in turn decreases the heat effect and stabilizes the migration rate.

For *isoelectric focusing* (IEF) (see later section), a power supply that provides constant power is advisable. During electrophoresis, current drops significantly because of lower conductivity as carrier ampholytes focus at their isoelectric points and because of creation of zones of pure water. If a constant-voltage supply is used, frequent voltage adjustments may be necessary. Constant-current power supplies are not customarily used in IEF. *Pulsed-power* or *pulsed-field* techniques (see later section) require a power supply that can periodically change the orientation of the applied field relative to the direction of migration.

Buffers

Buffer ions have a twofold purpose in electrophoresis; they carry the applied current, and they fix the pH at which electrophoresis is carried out. Thus they determine the kind of electrical charge on the solute, the extent of ionization of the solute, and therefore the electrode toward which the solute will migrate. The buffer's ionic strength determines the thickness of the ionic cloud (buffer and nonbuffer ions) surrounding a charged molecule, the rate of its migration, and the sharpness of the electrophoretic zones. With increasing concentration of ions, the ionic cloud increases in size, and the molecule becomes more hindered in its movement. For the separation of serum proteins, the barbital or tris-boric acid-EDTA buffers remain the most popular.

According to Joule's law, power produced when current flows through a resistive medium is dissipated as heat. This heat increases in direct proportion to the resistance but in proportion to the square of the current. The reduction in resistance caused by a high ionic strength buffer therefore leads to increased current and excessive heat. These buffers yield sharper band separations, but the benefits of sharper resolution are diminished by the Joule (heat) effect that leads to denaturation of heat-labile proteins or degradation of other components.

Ionic strength (also denoted by the symbol μ) is computed according to the following

$$\mu = 0.5\sum c_i z_i^2 \tag{8}$$

where

c_i = ion concentration in mol/L

z_i = the charge on the ion

The ionic strength μ of an electrolyte (buffer) composed of monovalent ions is equal to its molarity (mol/L). The ionic strength of a 1 mol/L electrolyte solution with one monovalent and one divalent ion is 3 mol/L, and for a doubly divalent electrolyte, it is 4 mol/L.

A relatively high ionic strength buffer ($\mu = 0.075$, pH 8.6) containing calcium lactate has been used in *high-resolution electrophoresis* to improve the separation of serum proteins into as many as 13 bands, with two or more bands in the α_1, α_2, and β-globulin regions and one or more additional bands seen in various pathological conditions. Because of higher conductivity and the associated heat produced, it is necessary to reduce the temperature of the system to 10 °C to 14 °C. "Submarine" techniques, in which gels are submersed in circulating buffer cooled by an external cooling device or a Peltier plate built into the electrophoresis chamber itself, provide exact temperature control. Effective cooling with less precise temperature control may also be achieved using chambers designed with a sealed compartment of cooled ethylene glycol, which is in contact with the gel during running.

Support Media

The support medium provides the matrix in which protein separation takes place. Various types of support media are used in electrophoresis and range from pure buffer solutions in a capillary to insoluble gels (e.g., sheets, slabs, or columns of starch, agarose, or polyacrylamide), or membranes of cellulose acetate. Gels are cast in a solution of the same buffer to be used in the procedure and may be used in a horizontal or vertical direction. In either case, maximum resolution is achieved if the sample is applied in a very fine starting zone. Separation is based on differences in charge-to-mass ratio of the proteins and, depending on the pore size of the medium, possibly molecular size.

Starch Gel

Starch gel is prepared from partially hydrolyzed native starch, which in raw form does not gel. It is used in starch

gel electrophoresis (SGE) to separate macromolecular ions on the basis of both charge-to-mass ratio and molecular size. Applying electrical current compacts proteins on the surface of the gel so that a thin uniform starting zone is produced, giving improved band resolution. However, because proper preparation of gels is relatively difficult and requires considerable skill, this technique is now rarely used in the clinical laboratory.

Cellulose Acetate

Cellulose acetate is a thermoplastic resin made by treating cellulose with acetic anhydride to acetylate the hydroxyl groups. The membranes contain about 80% air space within the interlocking cellulose acetate fibers and come as dry, opaque, brittle films that crack easily. When the film is soaked in buffer, the air spaces fill with liquid and the film becomes pliable. Membrane characteristics depend upon the extent of acetylation, the prewashing procedure used by the manufacturer, the additives used, the pore size, and the thickness of the membrane.

Samples (0.3 to 2.0 μL) are generally applied to cellulose acetate strips (presoaked with buffer) with a twin-wire applicator or the edge of a glass slide, and electrophoresis is carried out for 20 to 60 minutes. Stained membranes may be made transparent (cleared) for densitometry by soaking in a solvent containing 95 parts methanol and 5 parts glacial acetic acid. The cellulose acetate fibers are partially dissolved by the action of this solvent and coalesce to eliminate the original air spaces. Cleared membranes are strong and may be stored as a permanent record, but because of the necessity for presoaking before use and clearing the strips before densitometry, cellulose acetate has largely been replaced by agarose gel in most clinical applications.

Agarose

Agarose is a purified, essentially neutral fraction of agar obtained by separating agarose from agaropectin, a more highly charged fraction caused by acidic sulfate and carboxylic side groups. It is used in agarose gel electrophoresis (AGE) for the separation of serum, urine or CSF proteins, hemoglobin variants, isoenzymes, lipoproteins, and other substances. Because the pore size in agarose gel is large enough for all proteins to pass through unimpeded, separation is based only on the charge-to-mass ratio of the protein. Advantages of agarose gel include its lower affinity for proteins and its native clarity after drying, which permits excellent densitometric examination. It is essentially free of ionizable groups and so exhibits little endosmosis.

Most routine procedures for agarose electrophoresis today are carried out on commercially produced, prepackaged microzone gels, and the sample is applied by means of a thin plastic template with small slots corresponding to sample application points. The template is placed on the agarose surface, and 5- to 7-μL samples are placed on each slot. The serum sample is allowed to diffuse into the agarose for 5 minutes, excess sample is removed by blotting, and the template is removed. An AGE separation for most routine serum applications requires an electrophoresis time of 20 to 30 minutes.

Polyacrylamide Gel

Polyacrylamide is thermostable, transparent, strong, relatively chemically inert, and—depending on concentration—can be made in a wide range of pore sizes. Its average pore size in a typical 7.5% gel is about 5 nm (50 Å), large enough to allow most serum proteins to migrate unimpeded. However, proteins with a molecular radius and/or length that exceed critical limits will be impeded in their migration. Some of these proteins are fibrinogen, β-lipoprotein, α_2-macroglobulin, and γ-globulins. Thus separation is based on both charge-to-mass ratio and molecular size (a phenomenon referred to as molecular sieving), and serum proteins can be resolved into more individual fractions than with agarose gel. Furthermore, these gels are uncharged thus eliminating electroendosmosis, which is discussed later. Because of the potential carcinogenicity of acrylamide, however, appropriate caution must be exercised when handling this material during gel preparation.

Attempts to improve the hydrophilic nature of polyacrylamide have led to the development of mono- and di-substituted monomers, one of which is N-acryloyltris(hydroxymethyl)aminomethane or poly NAT™.[4] This material is more hydrophilic than polyacrylamide and its matrix has larger pores, thereby presenting less resistance to the passage of large molecules. It is ideally suited to the separation of DNA fragments up to 20 kilobases (kb) in size using a homogeneous (nonpulsed) electric field. Fragments that differ in size by as little as 2% can be resolved. Gels are submersed in buffer during use, allowing temperatures to be tightly controlled at values between 50 °C and 60 °C. Using elevated temperature results in shorter run times and more reproducible band migration.

Automated Systems

Because of increased volume of testing, primarily for serum proteins, many laboratories are converting to automated systems for electrophoresis. Such a system is the Helena SPIFE 3000, an automated electrophoresis system providing automated reagent application and a variety of gel sizes that permit the analysis of 10 to 100 samples simultaneously. It also features in-line sample application, automated electrophoretic separation and staining of analytes, multiple stain ports, and positive sample identification. Other systems that have partially automated the procedure or incorporated the ability to process multiple gels of different compositions sequentially include the Phast System (Pharmacia, LKB), the HITE Fractoscan (Olympus), the Hydragel-Hydrasys (Sebia), and the High-Performance Gel Electrophoresis (HPGE)-1000 system (LabIntelligence). Most CE systems (see Capillary Electrophoresis section) have autosampling capability for sequentially processing specimens, but the Beckman Coulter capillary zone electrophoresis (CZE)

system permits simultaneous processing of seven samples by using multiple capillaries. Newer microchip-based analyzers like the Agilent 2100 Bioanalyzer significantly miniaturize and increase the speed of the process for separating proteins, nucleic acids, or even entire cells. These advances substantially reduce the labor component associated with this technique.

General Operations

General operations performed in conventional electrophoresis include separation, detection and quantification, and a number of "blotting" techniques.

Electrophoretic Separation

When electrophoresis is performed on precast microzone agarose gels, the following steps are typical: (1) the excess buffer is first removed from the support surface by blotting, taking care that bubbles are not present; (2) 5 to 7 μL of sample is applied using a plastic template, allowed to diffuse into the gel, and then blotted to remove the excess (in some systems, samples may be applied with a comb); (3) the gel is placed into the electrode chamber; (4) electrophoresis is performed at specified current, voltage, or power; (5) the gel is rinsed, fixed, and then dried; (6) the gel is stained and redried; (7) the gel is scanned in a densitometer. If isoenzymes are the analyte, substrate-dye solution is incubated on the gel to stain zones before fixing and drying. Alternative procedures would be required if more sophisticated methods described later are used.

Detection and Quantification

Once separated, proteins may be detected either by staining followed by quantification using a densitometer or by direct measurement using an optical detection system.

Staining

If staining is used to visualize the separated proteins, the proteins are usually first fixed by precipitating them in the gel with a chemical agent like acetic acid and methanol. This prevents diffusion of proteins out of the gel when submersed in the stain solution. The amount of dye taken up by the sample is affected by many factors, such as the type of protein and the degree of denaturation of the proteins by the fixing agents.

Table 5-1 lists dyes commonly used in electrophoresis along with suggested wavelengths for quantitation by densitometry. Most commercial methods for serum protein electrophoresis use Amido Black B or members of the Coomassie Brilliant Blue series of dyes for staining. Isoenzymes are typically visualized by incubating the gel in contact with a solution of substrate, which is linked structurally or chemically to a dye before fixing. Silver nitrate and silver diammine stain proteins and polypeptides with sensitivity 10- to 100-fold greater than that of conventional dyes.[45] Selective fixing and staining of protein subclasses also can be achieved by combining a stain molecule with an antiglobulin as is done in immunofixation.

Quantification

Stained zones can be quantified in a *densitometer,* an instrument that measures the absorbance of each fraction as the gel (or other medium) is moved past a photometric optical system and displays an *electropherogram* on a recorder chart or computer display. Microprocessor-containing units automatically integrate the area under each peak and report each as a percent of total or as absolute concentration or activity computed from the total protein or activity of enzyme in the sample.

Reliable densitometric quantitation requires light of an appropriate wavelength, a linear response from the instru-

TABLE 5-1 Suggested Wavelengths for Quantitation of Protein Zones by Direct Densitometry

Separation Type	Stain	Nominal Wavelength (nm)
Serum proteins in general	Amido Black (Naphthol Blue Black)	640
	Coomassie BrilliantBlue G—250 (Brilliant Blue G)	595
	Coomassie BrilliantBlue R—250 (Brilliant Blue R)	560
	Ponceau S	520
Isoenzymes	Nitrotetrazolium Blue	570
Lipoprotein zones	Fat Red 7B (Sudan Red 7B)	540
	Oil Red O	520
	Sudan Black B	600
DNA fragments	Ethidium bromide (fluorescent)	254 (Ex) 590 (Em)
CSF proteins	Silver nitrate	—

ment, and a transparent background in the medium being scanned. The linearity may be tested with a neutral density filter designed with either separated or adjacent areas of linearly increasing density. The densities are permanent and have expected absorbance values. The very small sample sizes used and transparency of agarose gels satisfy the requirement for a clear background. Nevertheless, problems can occur with densitometry because of differences in quantity of stain taken up by individual proteins and differences in protein zone sizes.

Essential features of a densitometer include (1) the ability to scan gels 25 to 100 mm in length; (2) automatic gain control, which adjusts the most intense peak of an electropherogram to full scale; (3) automatic background zeroing, which selects the lowest point in the electropherogram as baseline so that minor peaks are not lost or "cut off"; (4) variable wavelength control over the range of 400 to 700 nm; (5) variable slits to allow adjustment of the beam size; (6) an integrating device with both automatic and manual selection of cut points between peaks; (7) automatic indexing, a feature that advances the electrophoresis strip from one sample channel to the next; and (8) the ability to measure ultraviolet fluorescence.

Desirable features of a densitometer include (1) computerized integration and printout, (2) built-in diagnostics for instrument troubleshooting, (3) a choice of one of several scanning speeds, and (4) ability to measure in the reflectance mode. Models with a separate personal computer for data processing permit storage and reformatting of data, if desired, and reprinting or delayed transmission to a host computer.

DNA analysis requires the ability to scan larger gels, which may contain several dozen bands of different length DNA fragments. Modern automated electrophoresis systems also use larger gels containing 30 or more samples, which are scanned on a new generation of densitometers referred to as "flat bed scanners" or "digital image analyzers."[17] These instruments are capable of scanning and storing digitized light intensity readings from large areas and use ultrasensitive charge coupled device (CCD) detectors having a resolution of up to 1200 dots per inch (21 μm). Sophisticated data processing software permits manipulation of the stored image information to produce conventional scans and computations or more complex outputs, such as overlaying and subtraction of patterns from two different samples. Chemiluminescence has also been used in this way to quantify IgE (Lumi-Phos 530).[54] DNA fragments have been detected by linking with a fluorescent dye label.[27]

Blotting Techniques

In 1975 Edward Southern developed a technique that is widely used to detect fragments of DNA. This technique, known as *Southern blotting*,[20] first requires an electrophoretic separation of DNA or DNA fragments by AGE. Next a strip of nitrocellulose or a nylon membrane is laid over the agarose gel, and the DNAs or DNA fragments are transferred or "blotted" onto it by either capillary, electro-, or vacuum blotting. They are then detected and identified by hybridization with a labeled, complementary nucleic acid probe. This technique is widely used in molecular biology for identifying a particular DNA sequence, determining the presence, position, and number of copies of a gene in a genome, and typing DNA (see Chapters 36 and 37 for further details).

Northern[20] and *Western*[20] blotting techniques, named by analogy to Southern blotting, were subsequently developed to separate and detect ribonucleic acid (RNAs) and proteins, respectively. Northern blotting is carried out identically to Southern blotting except that a labeled RNA probe is used for hybridization. Western blotting is used to separate, detect, and identify one or more proteins in a complex mixture. It involves first separating the individual proteins by polyacrylamide gel and then transferring or "blotting" onto an overlying strip of nitrocellulose or a nylon membrane by electro-blotting. The strip or membrane is then reacted with a reagent that contains an antibody raised against the protein of interest. (See Chapter 9 for further details and applications of this technique.)

Technical and Practical Considerations

In performing electrophoretic separations, a number of technical and practical aspects need to be considered as they affect the process.

Electroendosmosis or Endosmosis

An electrophoretic support medium, such as a gel in contact with water, takes on a negative charge caused by adsorption of hydroxyl ions. These ions are fixed to the surface and are immobile. Positive ions in solution cluster about the fixed negative charge sites, forming an ionic cloud of mostly positive ions and creating what is referred to as the Stern potential. The number of negative ions in the solution increases with increasing distance from the fixed negative charge sites until eventually positive and negative ions are present in equal concentration (Figure 5-2). The potential that exists between the fixed ions and the associated cloud of ions is termed the *electrokinetic potential* or the *zeta potential* (ζ).

When current is applied to such a system, charges attached to the immobile support remain fixed, but the cloud of ions in solution moves to the electrode of opposite polarity. Because ions in solution are highly hydrated, this results in movement of the solvent as well. The movement of solvent and its solutes relative to the fixed support is referred to as *endosmosis,* and it causes preferential movement of water in one direction. Macromolecules in solution that move in the direction opposite this flow may remain immobile or may even be swept back toward the opposite pole if they are insufficiently charged. In media in which endosmosis is strong, such as conventional cellulose acetate and conventional agarose gel, γ-globulins are swept back from the application point. Because the inner surface of a

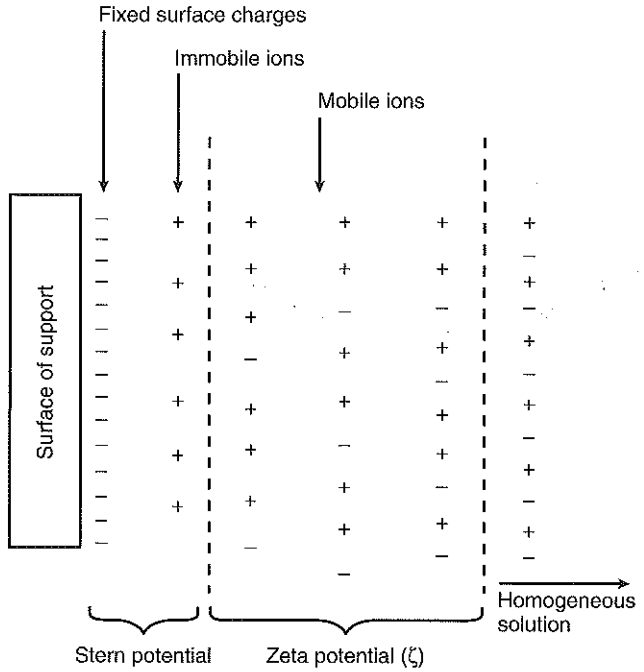

Figure 5-2 Distribution of + and – ions around the surface of an electrophoretic support. Fixed on the surface of the solid is a layer of – ions. (These may be + ions under suitable conditions.) A second layer of + ions is attracted to the surface. These two layers compose the Stern potential. The large, diffuse layer containing mostly + ions is the electrokinetic or zeta (ζ) potential. Extending farther from the surface of the solid is homogeneous solution. The Stern potential plus the zeta potential equals the electrochemical potential, or epsilon (ε) potential.

glass capillary contains many such charged groups, endosmosis is very strong and is actually the primary driving force for migration in CE systems.

Most of the endosmotic effect observed using agarose is caused by the presence of charged groups, such as sulfate or carboxylic acid groups. It is possible to reduce endosmotic effects considerably by removing or chemically modifying these charged groups. Endosmosis can be manipulated similarly in CE to modify the magnitude of the endosmotic effect. In electrophoretic media in which surface charges are minimal (starch gel, purified agarose gel, or polyacrylamide gel), endosmosis is also minimal.

Sampling

To achieve a proper balance between sensitivity and resolution, the amount of serum protein that is applied to an electrophoretic support must be optimum. Albumin is about 10 times more concentrated in serum than the smallest fraction, the α_1-globulins. Therefore the amount of serum applied should prevent overloading with albumin but still be adequate to quantify α_1-globulin. For the separation of serum proteins using polyacrylamide gel electrophoresis (PAGE), 3 µL of serum containing approximately 210 µg of total protein is applied. For alkaline phosphatase isoenzymes, up to 25 µL of a normal serum may be applied (less may be used if activity is greatly increased). Urine specimens require 50- to 100-fold concentration for adequate sensitivity, and CSF may or may not require concentration, depending on the staining approach used.

Discontinuities in Sample Application

Discontinuities in sample application may be caused by dirty applicators in cellulose acetate or inclusion of an air bubble in AGE. In practice, caution must be used in cleaning applicators because they are easily bent. Twin-wire applicators are best cleaned merely by agitating in water followed by gently pressing the applicators against absorbent paper. It is inadvisable to clean wires by manual wiping. The pipette tip should be checked for air bubbles before application of the sample to the agarose gel template.

Unequal Migration Rates

Unequal migration of samples across the width of the gel may be caused by dirty electrodes causing uneven application of the electric field or by uneven wetting of the gel. If wicks are used to connect the gel to a power supply, uneven wetting of the wicks could cause unequal migration or bowing of sample lanes at the gel edges. Gels, which may have been stored too close to heat sources (e.g., in a cabinet over a light fixture), could have partially and unevenly dried areas, contributing to similar problems.

Distorted, Unusual, or Atypical Bands

Distorted protein zones may be caused by bent applicators, incorporation of an air bubble during sample application, overapplication, or inadequate blotting of the sample. Distorted zones may also be caused by excessive drying of the electrophoretic support before or during electrophoresis or by improper tension on a cellulose acetate film, resulting in zones that look "bent over." Irregularities (other than broken zones) in the sample application probably are due to excessively wet cellulose acetate films or agarose gels. Parts of the applied samples may look washed out.

In most cases, unusual bands are artifacts that may be easily recognized. Hemolyzed samples are frequent causes of an increased β-globulin (where free hemoglobin migrates) or an unusual band between the α_2- and β-globulins, the result of a hemoglobin-haptoglobin complex. A band occurring at the starting point of an electropherogram may be fibrinogen. The sample should be verified as being serum before this band is reported as an abnormal protein. The α- and β-lipoproteins may migrate ahead of their normal positions in some samples. Occasionally a split albumin zone is observed in the rare, benign, genetically related condition of *bis*albuminemia. However, a grossly widened albumin zone could be due to albumin-bound medication and not faulty electrophoretic practice.

Atypical bands in an isoenzyme pattern may be the result of binding by an immunoglobulin (a macroenzyme),

causing abnormal migration of one or more of the normal isoenzymes. Occasionally an irregular but sharp protein zone is seen at the starting point. Unlike fibrinogen or other proteins that may be seen at about the same point, the artifact lacks the regular, somewhat diffuse appearance that proteins normally show; it is actually denatured protein resulting from a deteriorated serum. Of course when faced with an unusual band anywhere in a serum protein pattern, the possibility that it is a true paraprotein must always be considered. Finally, it is good laboratory practice to include a control serum with each electrophoretic run to evaluate its quality and that of the densitometer.

Buffers

Because buffers used in electrophoresis are good culture media for the growth of microorganisms, they should be refrigerated when not in use. Moreover, a cold buffer is preferred in an electrophoretic run, because it improves resolution and decreases evaporation from the electrophoretic support. Buffer used in a small-volume apparatus should be discarded after each run because of pH changes resulting from the electrolysis of water that accompany electrophoresis. If volumes used are larger than 100 mL, buffer from both reservoirs may be combined, mixed, and reused up to four times.

Staining

In practice, a typical stain solution may be used several times before being replaced. A good rule of thumb is that a stain solution of 100 mL may be used for a combined total of 387 cm^2 (60 in^2) of cellulose acetate or agarose film. The stain solution may be considered faulty if leaching of stained protein zones occurs in the 5% acetic acid wash solution or in the clearing solution (cellulose acetate only). Whenever protein zones appear too lightly stained, the stain or substrate reagent—in the case of isoenzymes—should always be suspected. Stain solution must be stored tightly covered to prevent evaporation.

Types of Electrophoresis

Using different media in different physical formats and a variety of instrumental configurations, several different types of electrophoretic techniques are used for the separation of a diverse range of analytes.

Slab Gel Electrophoresis

Traditional methods, using a rectangular gel regardless of thickness, are referred to collectively by the term *slab gel electrophoresis.* Its main advantage is its ability to simultaneously separate several samples in one run. Starch, agarose, and polyacrylamide media have all been used in this format. It is the primary method used in clinical chemistry laboratories for separation of various classes of serum or CSF proteins and DNA and RNA fragments. Gels (usually agarose) may be cast on a sheet of plastic backing or completely encased within a plastic walled cell, which allows either horizontal or vertical electrophoresis and submersion for cooling, if necessary.

Slab gels may be cast with additives such as (1) ampholytes, which create a pH gradient (see Isoelectric Focusing Electrophoresis), or (2) sodium dodecyl sulfate (SDS), which denatures proteins (see Two-Dimensional [2-D] Electrophoresis). In some applications, a gradient of concentration or denaturant is created in the gel to improve separation.[12] Very thin gradient or nongradient gels have been used to improve the efficiency and speed of separation of DNA fragments.[52,61] In addition to conventional serum proteins, applications include the separation of isoenzymes, lipoproteins, hemoglobins, and fragments of DNA and RNA. One-dimensional separations of the last two often involve the addition of a mixture of known fragment size markers, referred to as a ladder, in one lane to enable size identification of sample fragments.

Disc Electrophoresis

Protein electrophoresis using agarose gel yields only five zones, namely: (1) albumin, (2) α_1-, (3) α_2-, (4) β-, and (5) γ-globulins, although some subfractionation of the α_2- and β-globulins is possible with high resolution gels. *Disc electrophoresis* was developed to improve this situation and derives its name from *discontinuities* in the electrophoretic matrix caused by layers of gel that differ in composition and pore size.[7,40] The pore size in a polyacrylamide or starch gel is controlled by the percent composition of the polyacrylamide or starch and is much smaller than that found in agarose gel. These gels may yield 20 or more fractions and are widely used to study individual proteins in serum, especially genetic variants and isoenzymes.

With PAGE, samples are separated in individual gels prepared in open-ended glass tubes, which form a bridge between two buffer reservoirs. Although precast gel tubes are now commercially available, the original technique involved a three-gel system prepared in situ. A small-pore *separation gel* filled the majority of the tube followed, after gelation, by a thin segment of large-pore *spacer gel* cast on top of the separation gel. Then another thin layer of large-pore monomer solution containing a small amount of serum, about 3 µL, was polymerized above the spacer gel. When electrophoresis begins, all protein ions migrate easily through the large-pore gels (which do not impede movement of most proteins in serum) and stack up on the separation gel in a very thin zone. This process improves resolution and concentrates protein components at the border (or starting zone) so that preconcentration of specimens with low protein content (e.g., CSF) may not be necessary. Separation then takes place in the bottom separation gel with retardation of some proteins caused by the molecular sieve phenomenon. A schematic representation of serum protein electrophoresis by PAGE is shown in Figure 5-3.

Isoelectric Focusing Electrophoresis

IEF separates amphoteric compounds, such as proteins, with increased resolution in a medium possessing a stable pH gradient. The protein becomes "focused" at a point on the gel as it migrates to a zone where the pH of the gel matches

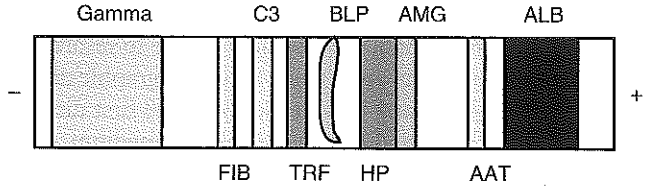

Figure 5-3 A simplified schematic drawing of a protein pattern from the serum of a subject with haptoglobin type 2-1 (separation by PAGE). Some zones contain more than the one protein shown, as demonstrated by immunological techniques. *AAT*, Alpha$_1$-antitrypsin; *ALB*, albumin; *AMG*, alpha$_2$-macroglobulin; *BLP*, beta-lipoprotein; *C3*, complement 3; *FIB*, fibrinogen; *gamma*, gamma-globulin; *HP*, haptoglobin; *TRF*, transferrin.

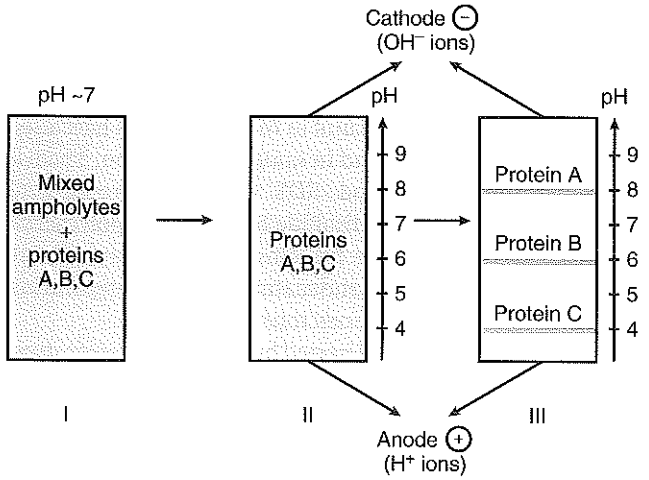

Figure 5-4 Schematic of an IEF procedure. **I,** A homogeneous mixture of carrier ampholytes, pH range 3 to 10, to which proteins A, B, and C with pI 8, 6, and 4, respectively, were added. **II,** Current is applied and the carrier ampholytes rapidly migrate to the pH zones where the net charge is zero (the pI value). **III,** The proteins A, B, and C migrate more slowly to their respective pI zones where migration ceases. The high buffering capacity of the carrier ampholyte creates stable pH zones in which each protein may reach its pI.

the protein's isoelectric point (pI). At this point, the charge of the protein becomes zero and its migration ceases. Figure 5-4 illustrates the procedure and shows the electrophoretic conditions before and after current is applied. The protein zones are very sharp, because the region associated with a given pH is very narrow. Normal diffusion is also counteracted by the acquisition of a charge as a protein varies from its pI position and subsequently migrates back because of electrophoretic forces (Figure 5-5). Proteins that differ in their pI values by only 0.02 pH units have been separated by IEF.

The pH gradient is created with *carrier ampholytes*, a group of amphoteric polyaminocarboxylic acids, which have slight differences in pKa value and molecular weights of 300 to 1000. Mixtures of 50 to 100 different compounds

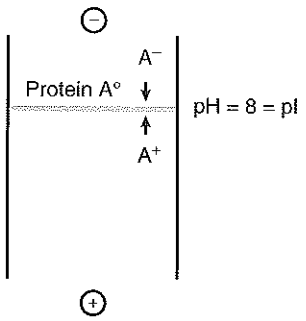

Figure 5-5 After attaining the pH where protein A has a net charge of zero (A°), diffusion toward the cathode bestows a negative charge on A (A^-), and migration in the electric field forces A^- back to A°. Diffusion toward the anode causes A to take on the opposite charge A+, and migration is toward the cathode and to the point where A° exists. IF processes of this kind cause sharp zones to form (i.e., the protein is focused).

are added to the medium and create a "natural pH gradient" when the individual ampholytes reach their pI values during electrophoresis. They establish narrow buffered zones, with stable but slightly different pHs, through which the slower-moving proteins migrate and stop at their individual pIs.

As Figure 5-4 illustrates, the anode is surrounded by a dilute acid solution and the cathode by a dilute alkaline solution. After focusing, the most negatively charged carrier ampholytes and proteins will be found at the anodal end and the most positively charged near the cathodal end of the electrophoretic matrix. The other carrier ampholytes and proteins focus at intermediate points according to their isoelectric points. Because carrier ampholytes are generally used in relatively high concentrations, a high-voltage power source (up to 2000 V) is necessary (power is in the vicinity of 2 to 50 W, depending on experimental conditions). As a result, the electrophoretic matrix must be cooled. A modification of this technique, in which an immobilized pH gradient (IPG-IEF) is produced in the gel before applying the sample, is reported to improve resolution and reproducibility.[11]

PAGE-IEF is widely used in analytical work as it is essentially free of electroendosmosis. The polyacrylamide gel must have a large enough pore size, however, so that protein migration will not be impeded by molecular sieving effects. In actual practice, impeded migration of some proteins, such as IgM, cannot be prevented. With the availability of endosmosis-free materials, IEF methods have been adapted for agarose, cellulose acetate, and Sephadex electrophoresis. AGE-IEF and cellulose acetate electrophoresis-IEF (CAE-IEF) have the advantages that operating conditions are simple, and that large pore sizes make it unlikely that any proteins will be excluded on the basis of molecular size.[9] Sephadex, like polyacrylamide, provides advantages of separation on the basis of molecular size. IEF has been applied

to the separation of alkaline phosphatase isoenzymes and is widely used in neonatal screening programs to test for variant hemoglobins (see Chapter 31).

Isotachophoresis

ITP completely separates smaller ionic substances into adjacent zones that contact one another with no overlap, and all migrate at the same rate. In this technique, no background electrolyte (buffer) is mixed with the sample, so current flow is carried entirely by charged sample ions. An aliquot of a sample is typically placed in a capillary between a leading electrolyte solution that contains faster-migrating ions than any in the sample and a trailing solution containing slower-migrating ions than any in the sample. Once a faster-moving component separates completely from a slower-moving one, any further separation creates a region of depleted charge and increases the resistance and therefore the local voltage in that region. The increased voltage causes the slower component to migrate faster and close the gap, thereby concentrating it and increasing the conductivity of its zone until it matches that of the faster ion. Ultimately, all ions migrate at the rate of the fastest ion in zones that differ in size depending on their original concentrations. Zone size is determined by measuring ultraviolet (UV) absorbance, temperature difference, or conductivity as the sample passes a detector. Applications include the separation of small anions and cations, organic and amino acids, peptides, nucleotides, nucleosides, and proteins.

Pulsed-Field Electrophoresis

In pulsed-field electrophoresis, power is alternately applied to different pairs of electrodes or electrode arrays, so the electrophoretic field is cycled between two directions. The directions can differ spatially by 105° to 180°, and molecules must reorient themselves to the new field direction during each cycle before migration can continue. Because reorientation time depends on molecular size, net migration becomes a function of the frequency of field alteration. This permits separation of very large molecules, such as DNA fragments greater than 50 kb that cannot be resolved by the relatively small pores in agarose or polyacrylamide gels.[39] Fragments of 50 to 400 kb can be resolved using 10 s pulse times, whereas larger fragments up to 7 megabases in size or intact chromosomes require pulse times of several hours for complete resolution. This technique has been applied to typing various strains of bacterial DNA.[15,46]

Two-Dimensional (2-D) Electrophoresis

Two-dimensional (2-D) electrophoresis is extensively used in the field of proteomics to study families of proteins and search for genetic- or disease-based differences or to study the protein content of cells of various types.[29] It has also been applied to the study of human gene mutations[55] and the DNA of various bacteria and tumor cells as a means to earlier diagnosis.[12,44] By combining charge-dependent IEF in the first dimension with molecular weight–dependent electrophoresis in the second, the technique is able to resolve up to 1100 separate protein spots using autoradiographic detection and up to 400 using Coomassie dyes. The first dimension separation is carried out in a large-pore medium, such as agarose gel or large-pore polyacrylamide gel. The second dimension is often polyacrylamide in a linear or gradient format.

The 2-D electrophoresis method of O'Farrell[38] uses PAGE-IEF in 130 × 2.5-mm (internal diameter) tubes for the first dimension and covers a pH range of 3 to 10 units. The anodal compartment is in contact with 10 mmol/L phosphoric acid and the cathodal compartment with 20 mmol/L NaOH. After electrophoresis is complete, the gel is extruded from the tube and placed in contact with a thin, polyacrylamide gradient gel slab that incorporates SDS. At the end of the process, the polypeptides are detected by one of several different methods.

In the O'Farrell method, SDS is used in the second dimension, β-mercaptoethanol in the first. Others have used SDS in both dimensions and in sample preparation. The use of β-mercaptoethanol and SDS denatures proteins to polypeptides by reducing disulfide bonds and depolymerizing proteins. When native proteins, such as enzymes, are desired for further study, nondenaturing sample preparation and electrophoresis conditions must be used.

Separated proteins are detected by use of Coomassie dyes, silver staining, radiography (exposure of photographic film to emissions of isotopically labeled polypeptides), or fluorographic analysis (x-ray film exposed to tritium-labeled polypeptides in the presence of a scintillator). The latter two methods represent the greatest analytical sensitivity, because they are 100 to 1000 times more sensitive than the Coomassie dyes.

Newer developments in this area combine analytical techniques to achieve a 2-D separation by linking, for example, liquid IEF with nonporous silica reverse phase, high performance liquid chromatography (HPLC; see Chapter 6) and detecting intact proteins by electrospray ionization, time of flight, and mass spectrometry[57] (see Chapter 7).

CAPILLARY ELECTROPHORESIS

In CE, the classic techniques of zone electrophoresis, ITP, IEF, and gel electrophoresis are carried out in a small-bore (10- to 100-μm internal diameter) fused silica capillary tube of 20 to 200 cm in length.[36]

Two distinct advantages of the capillary format include the ability to apply much higher voltages than in traditional electrophoresis and the ease of automation. Applications are also more extensive and include separation of low-molecular-weight ions in addition to proteins and other macromolecules. Even uncharged molecules can be separated using CE in the micellar electrokinetic chromatography (MEKC) mode that is discussed later in this section. CE has also proved useful for separations of inorganic ions, amino

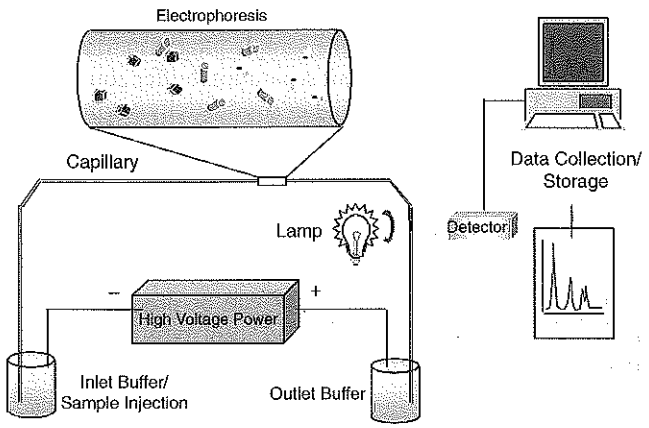

Figure 5-6 A schematic for CE instrumentation.

acids, organic acids, drugs, vitamins, porphyrins, carbohydrates, oligonucleotides, proteins, and DNA fragments.[8,22,51,60]

Instrumentation

A schematic diagram of a typical CE instrument is shown in Figure 5-6. As indicated, the capillary tube serves as an electrophoretic chamber that is connected to a detector at its terminal end and, via buffer reservoirs, to a high-voltage power supply. Improved heat dissipation permits the application of voltages in the range of 10 to 30 kV, which enhances separation efficiency and reduces separation time in some cases to less than 1 minute. Only a few microliters of the sample are required, with volumes in the picoliter to nanoliter range actually used. This minimizes distortions in the applied field caused by the presence of samples.

In contrast to the cumbersome and time-consuming tasks of conventional electrophoresis, CE is well suited to automation. Samples are easily applied to the capillary, a variety of detector types can be used, and the resulting electropherotograms can be analyzed and manipulated in much the same manner as chromatograms. Commercial instruments resemble many HPLC instruments in terms of automated sample loading and data analysis. Traditional serum protein electrophoresis, for example, can be fully automated with CE.

The Capillary Format

The capillary tubes used as separation chambers in CE are most commonly made from fused silica (i.e., pure glass) coated with a thin exterior covering of polyimide to provide strength and flexibility. Although capillaries can be made from other materials, such as polyethylene or Teflon, such capillaries have seen limited use. The polyimide coating is usually removed from a small portion of the capillary towards the terminal end, creating a window for online optical detection. Caution must be taken with capillaries after a detection window has been created since loss of the polyimide coating from the capillary tubing weakens the wall of the tube in these locations. The outer diameter of the capillary tubing typically varies from 180 to 375 μm, the inner diameter from 20 to 180 μm, and the total length from 20 cm up to several meters. Noncylindrical capillary tubing suitable for CE is now available from some commercial providers. For example, rectangular capillaries (Polymicro Technologies, Phoenix) provide a flat surface that is more amenable to optical detection than their curved counterparts.

The main advantage of performing electrophoresis in a narrow-bore capillary comes from efficient heat dissipation. The relatively poor dissipation of Joule heat in traditional electrophoresis limits it to relatively low electric fields. The large surface-to-volume ratio inherent in capillaries, however, allows for more effective heat dissipation and much higher voltages can be applied, often up to 30 kV.[33] An additional advantage gained from using a narrow-bore capillary chamber is that it improves resolution by minimizing band broadening.

Sample Injection

In CE, sample volumes of 1 to 50 nL are loaded into the capillary chamber by one of two primary methods, *hydrodynamic injection* and *electrokinetic (EK) injection.* In practice, to maintain high separation efficiency, the sample plug length is usually less than 2% of the total capillary length. With hydrodynamic injection, an aliquot of a sample is introduced by applying a positive pressure at the inlet vial or alternately vacuum at the outlet vial. The volume of sample loaded is governed by a number of parameters including (but not restricted to) the inner diameter of the capillary, buffer viscosity, applied pressure, temperature, and time. Alternatively, gravity may be used as the source of pressure by raising the inlet vial (or lowering the outlet vial) and allowing "siphoning" to occur for a timed interval.

With EK injection, an aliquot of a sample is introduced by applying a voltage for a timed interval. The magnitude of the voltage is dependent on the analyte and buffer system used but typically involves a field strength 3 to 5 times lower than that used for separation. It is important to note that although hydrodynamic methods introduce a sample representative of the bulk specimen, EK injection favors the preferential movement of more mobile ions into the capillary.

Direct Detection

With CE, separated analytes are detected and measured as they migrate past an optical detector without prior staining. Optical detection is based on classical methods, such as photometric absorbance, refractive index, and fluorescence (see Chapter 3). These techniques miniaturize and simplify the process of measurement by eliminating several of the steps required in conventional gel electrophoresis. Because the amount of protein measured and the measurement path are both very small, however, special conditions are often used to improve sensitivity.

Optical Detection

As with HPLC, ultraviolet-visible photometers are widely used as detectors to monitor CE separations.[42] To interface such online detectors with the capillary, a "detection window" is created towards the outlet end of the capillary tube. The "window" serves as an inline cuvet and is typically formed by burning off the polyimide with a small flame and cleaning the window with ethanol. It is not recommended that the polyimide be removed (by scraping) with a sharp object because this could scratch the surface of the fused silica and interfere with optical detection. Although this configuration allows for high efficiency separation because there is no band broadening caused by component mixing or dead volume, the inner diameter of the capillary tube defines the optical light path (OLP) length of the in-line cuvet. Since absorbance is directly proportional to the length of the cuvet (OLP) used in an optical system (see Chapter 3), the 20 to 100 μm inner diameter limits UV-visible absorbance detection to the 10^{-6} to 10^{-8} M range.

Improving Limits of Detection

A number of approaches have been devised to improve the limit of detection of online CE detectors. These include increasing the length of the OLP, using more sensitive optical techniques, and preconcentrating the sample.

Increased OLP. Capillary tubes modified at the detector window with a "bubble" cell (a glass-blown expansion of the internal diameter of the capillary tube) can expand the OLP by almost an order of magnitude, with a concomitant lowering of the system's limit of detection. Alternatively a "Z" geometry has been developed that increases the OLP via detection down the core of the capillary with lengths up to 1 mm possible.

Sensitive Optical Detectors. More sensitive optical techniques that have been used with CE include fluorescence, refractive index, chemiluminescence, Raman spectrophotometry, and circular dichroism.[51] The most sensitive optical detection method used in CE is laser-induced fluorescence (LIF), which is capable of detection limits in the 10^{-18} to 10^{-21} mol (or better) range. This detection mode is easily accomplished with analytes that are either easily labeled with a fluorescent substrate (e.g., intercalators for double-stranded DNA) or are naturally fluorescent (e.g., proteins or peptides containing tryptophan). CE systems have also been interfaced with mass spectrometers,[48] and electrochemical detection methods[13] have been developed, although such detectors must be isolated electrically from the electrophoretic voltages.

Online Sample Concentration. Another technique used in CE systems to increase their limit of detection is to preconcentrate the sample. One of the simplest methods for sample preconcentration is to induce a "stacking" effect with the sample components, something easily accomplished by exploiting the ionic strength differences between the sample matrix and separation buffer.[5] This results from the fact that sample ions have decreased electrophoretic mobility in a higher conductivity environment. When voltage is applied to the system, sample ions in the sample plug instantaneously accelerate toward the adjacent separation buffer zone. Upon crossing the boundary, the higher conductivity environment induces a decrease in electrophoretic velocity and subsequent "stacking" of the sample components into a smaller buffer zone than the original sample plug. Within a short time, the ionic strength gradient dissipates and the charged analyte molecules begin to move from the "stacked" sample zone toward the cathode. Stacking can be used with either hydrostatic or EK injection and can typically yield a tenfold enhancement in sample concentration and hence sensitivity.

An alternative approach to stacking is a "focusing" that is based on pH differences between the sample plug and separation buffer. This has been shown to be very useful for the analysis of peptides, mainly caused by their relative stability over a wide pH range.[1] By increasing the pH of the sample above that of the net pI of the analytes of interest and flanking the sample plug with low pH separation buffer zones (i.e., an equivalent volume of low pH separation buffer following introduction of the sample plug), the negatively charged peptides are electrophoretically driven toward the anode. Upon entering the lower pH separation buffer, a pH-induced change in their charge state causes a reversal in their electrophoretic mobility, resulting in a "focusing" of the peptides at the interface of the sample (high pH) and low pH buffer plugs (similar to those in isoelectric focusing). After the pH gradient dissipates, the peptides, again positively charged, migrate toward the cathode as a sharp zone. This approach can be applied to a variety of analytes, but is limited to those that can withstand the inherent changes in pH without substantial denaturation and may yield as much as a fivefold enhancement in a system's limit of detection.[50]

Other types of sample concentration enhancement approaches applicable to CE include ITP[56] and those involving concentration on an online solid phase.[43] This latter method shows much promise for both small and large molecules and is covered in detail in the review by Wettstein and Strausbauch.[58]

Indirect Detection

When strong chromophores are lacking in the analyte of interest, absorbance and fluorescence detection can also be used in an indirect mode.[10,26,34] In this mode of detection, a strongly absorbing ion is added to the running electrolyte and monitored at a wavelength that gives a constant, high background absorbance. As solute ions move into their discrete zones during the electrophoretic process, they displace the indirect detection agent through mutual repulsion, and this produces a decrease in the background absorbance as the zone passes through the detector. Reagents with the appropriate fluorescence properties can also be employed in a similar manner. The indirect detection of amino acids by CE has been demonstrated with the potential for use in

diagnosis of aminoacidurias.[30] These investigators show the direct extrapolation of this technique to microchip detection where UV detection is difficult, if not impossible.

Technical Considerations

Temperature and surface effects influence the separation capabilities of CE. Artifacts also can arise with CE.

Temperature Effects

In most slab or tube platforms for electrophoresis, moderate electric fields (up to 1000 volts) are used because the Joule heating that accompanies the use of higher field strengths can cause nonuniform temperature gradients, local changes in viscosity, and subsequent zone broadening. CE is distinguished from other forms of electrophoresis by the fact that extraordinarily high fields (30,000 volts) can be used to obtain rapid, high efficiency separations. The problems encountered with noncapillary platforms are prevented because of the effective dissipation of Joule heat by either forced air convection or liquid cooling of the capillary, both of which are possible because of the narrow bore of the capillary. The Joule heat produced is a function of the buffer type, concentration, voltage applied, capillary inner diameter, and length, and can be determined for any given system by generating an *Ohm's law plot,* which allows for easy determination of the maximum voltage that can be used effectively.[32] Although the heat produced by the electrophoretic process can be decreased by reducing the inner diameter of the capillary, the ionic strength of the running buffer, or the applied voltage, the latter is less desirable since resolution is directly proportional to the applied field. Consequently, attempts should be made to alter other parameters before reducing the field.

Surface Effects

As in electrophoresis in general, the flow of liquid (electroosmotic or electroendosmotic flow [EOF]) in CE is a consequence of surface charge on the solid support. In CE it plays a significant role in the separation process. The charge on the inner surface of a fused silica capillary is determined by the ionization state of the silanol groups (SiOH) that populate it. Interaction of positively charged buffer species with the bound surface anions generates a layer of mobile cations that move toward the cathode when voltage is applied. This induces a very strong EOF that carries all analytes in the same direction, regardless of their charge. Separation is then achieved because of differences in the electrophoretic migration rates of the analytes superimposed on this EOF.

Because the driving force of the flow is distributed along the wall of the capillary, the flow profile is nearly flat or plug-like, contrasting the laminar or parabolic flow generated by a pressure-driven system caused by shear forces at the wall. A flat flow profile is beneficial because it does not contribute to the dispersion of solute zones. The magnitude and direction of the EOF can be impacted by the type of electrolyte used, the pH, the ionic strength, the use of additives (e.g., surfactants and organic solvents), and the polarity and magnitude of the applied electric field.

Although advantageous for dissipation of Joule heat, the large surface area-to-volume ratio of the capillary chamber increases the likelihood of analyte adsorption onto the surface of its inner wall. This causes phenomena such as peak tailing and even total and irreversible adsorption of the analyte. Adsorption is typically between cationic solutes and the negatively charged wall of the capillary chamber, primarily through ionic interactions (with silanols), but can also involve hydrophobic interactions (with siloxanes). Because of the numerous charges and hydrophobic regions, significant adsorptive effects have been noted, especially for proteins. In practice, adsorption of substances, whether from the sample or from the buffer, to the inner surface of the capillary can alter migration times and other separation characteristics; unaddressed, the capillary can eventually become fouled. Buffer components, such as surfactants, can often render permanent changes to the inner surface of the capillary (through adsorption) and may warrant dedication of specific capillaries for use with particular surfactants.

To minimize these inner wall effects, capillary chambers are conditioned by chemical treatment, most commonly with base to remove adsorbates and refresh the surface. A typical wash method includes flushing the chamber with 10 to 20 capillary volumes of 0.1 to 1.0 mol/L NaOH, followed by flushing with running electrolyte. To prevent exposing the capillary surface to drastic fluctuations in the pH, conditioning procedures for separations at low pH may be better served by using strong acids (e.g., HNO_3), surfactants (e.g., SDS), or organic solvents, such as acetonitrile or methanol, may also be warranted with certain separations.

Artifacts

Because CE uses online optical detection, artifacts can result in the form of "system peaks." These often originate from the sample or the interfaces between the sample and the separation buffer because any species that absorbs at the detection wavelength will generate a response. This differs from protein slab gel electrophoresis where detection specificity is governed by a protein specific stain. It is not uncommon, for example, for buffer species present in the sample but not in the separation buffer to generate system peaks. However, clinical serum protein electrophoresis provides one example where artifacts are eliminated by CE.

One problem associated with conventional electrophoresis of serum proteins is its proclivity for point-of-application artifacts. These are bands that result from the fact that electrophoretic mobility (e.g., with AGE) is bidirectional from the point of application. Consequently the point of application remains part of the scanned area of interest. The fact that these must be immunotyped to distinguish real monoclonal proteins from artifacts is costly and time consuming.

CE prevents point-of-application artifacts for two reasons. First, the net mobility in CE is the vectorial addi-

tion of both protein electrophoretic mobility and the EOF. As a result of this unidirectional movement (toward the detector), the point-of-application remains remote from the detector. Second, unlike AGE where precipitates cannot exit the loading well and enter the gel (thus appearing as a band in the scanned region of the gel), there is no gel matrix in CZE to impede electrophoretic migration since analysis occurs in free solution (i.e., CZE). This was demonstrated by Clarke et al who evaluated a small subset of serum samples containing monoclonal proteins that remained at the point-of-application on agarose gels (and cellulose acetate) but were handled by CZE with ease.[3] These precipitates may be euglobulin or cryoprecipitates and may or may not contain a monoclonal protein; only immunoelectrophoresis or immunofixation can determine the presence of monoclonal proteins.

Modes of Operation

Modes in which CE systems are operated include (1) CZE, (2) MEKC, (3) capillary gel electrophoresis (CGE), (4) capillary IEF, and (5) capillary ITP.

Capillary Zone Electrophoresis

CZE, also called *open-tube* or *free-solution* CE, is the simplest form of CE. It includes *capillary ion electrophoresis,* which refers to the analysis of inorganic ions by CZE, particularly when indirect detection is used. The power of the CZE mode is the ability to resolve charged species electrophoretically without a sieving matrix; this applies to a broad spectrum of analytes ranging from proteins, peptides, and amino acids to small molecules (e.g., drugs) and ions. There is abundant literature denoting the advantages of CZE for serum protein analysis over AGE and even CAE.[18,19,37] Figure 5-7 shows a comparison of the separation of serum proteins by cellulose acetate (CAE), agarose (AGE), and CE. The presence of the classical zones with CE is apparent, albeit in a reversed order, as is the identification of serum protein abnormalities in gamma regions. Retrospective studies have shown CE to be effective for detecting monoclonal proteins, which could then be immunotyped by conventional techniques (IF and IEP).[37] Moreover, one study demonstrated the utility of CE for doing both the serum protein electrophoresis and immunotyping for greater than 1500 serum samples.[19] These and other studies lead to the same conclusions—that CE is more sensitive than AGE for identifying abnormalities.

Micellar Electrokinetic Chromatography

MEKC is a hybrid of electrophoresis and chromatography. MEKC, a mode that is separate and distinct from capillary electrokinetic chromatography (CEC), is an effective electrophoretic technique, because it can be used for the separation of neutral and charged solutes. The separation of neutral species is accomplished by the use of micelles formed in the running buffer, when the concentration of surfactant exceeds the critical micelle concentration (e.g., 8 to 9 mmol/L for SDS). During migration the micelles can interact with analytes in a chromatographic manner through hydrophobic interactions in which analytes are micellized based on their degree of hydrophobicity. With charged micelles (e.g., SDS), analytes can also interact through electrostatic interactions via the charge on the surface of the micelle. For neutral species, only partitioning in and out of the micelle affects the separation.

Capillary Gel Electrophoresis

CGE is directly comparable to traditional slab or tube gel electrophoresis because the separation mechanisms are identical. The size separation is achieved with a suitable polymer, which acts as a molecular sieve or sizing mechanism. As charged analytes migrate through the polymer network, they become hindered to a degree that is governed by their size (larger solutes hindered more than smaller ones). Macromolecules, such as DNA and SDS-saturated proteins, cannot be separated without a gel or some other separation mechanism, because they contain mass-to-charge ratios that do not vary with size. The term "gel" in CGE is a misnomer, primarily because cross-linked "gels," as we know them in slab format, are not routinely used in CE. A more suitable term might be "sieving matrix" or "soluble polymer network," a linear polymeric structure that is soluble, reasonably low viscosity, and capable of self-entangling in a manner that forms

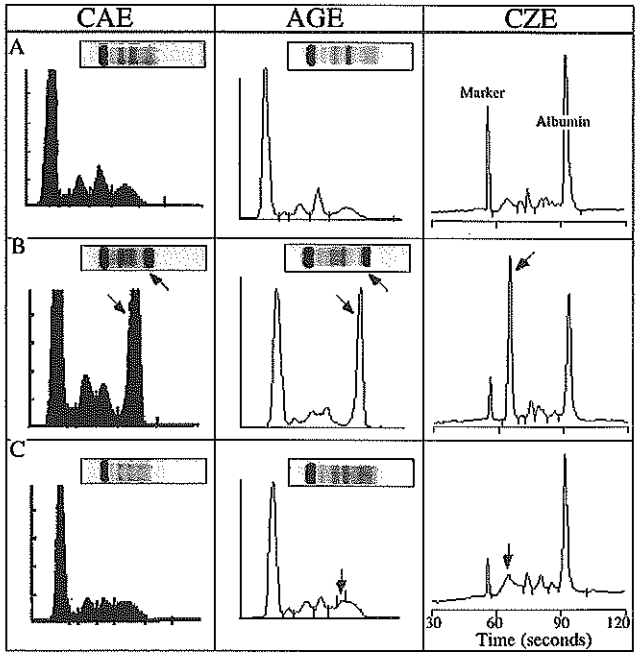

Figure 5-7 Rapid protein electrophoresis of serum protein; comparison with scanning densitometry profiles obtained from CAE and AGE electrophoresis. Panel A—normal serum, Panel B—patient serum containing a large M-protein; Panel C—patient serum containing a small monoclonal protein. The arrows indicate the position of the monoclonal proteins.

pores through which sieving can occur. A variety of polymeric matrices have been defined for both DNA (polyacrylamide and cellulosic materials) and protein analysis (e.g., dextran-base matrices). One of the requirements that often accompanies this type of analysis is to reduce electroosmotic flow. This is accomplished by covalently, adsorptively, or dynamically coating the surface. Cross-linked polyacrylamide has been the main polymer of choice for this but more recently has been supplanted by a host of polymeric matrices that not only provide effective molecular sieving but also adsorptively coat the capillary surface.[23,53] An example of a CGE separation of DNA is provided in a later section.

Capillary Isoelectric Focusing Electrophoresis

cIEF is comparable to tube IEF and is governed by the same principles and procedures. It differs from conventional IEF in that it can be carried out using either a free solution of ampholytes or a precast gel. As expected with a CE mode and unlike conventional IEF, the focused zones migrate past the online detector either during the focusing process or following it. Figure 5-8 shows an example of this where the separation by cIEF is completed in ~15 minutes, circumventing conventional IEF protocols and/or the necessity for other electrophoretic methods (e.g., CAE), both of which are much less time efficient.[14]

Capillary Isotachophoresis

Capillary ITP has essentially the same features as ITP in other formats, except that conditions of pure ITP are usually not achieved. This is not commonly used as a bonafide CE mode, but instead it is more typically used for online sample preconcentration (as described earlier). Most of the time it functions as a preconcentrating step in a mixed mode with CZE, MEKC, or CGE.

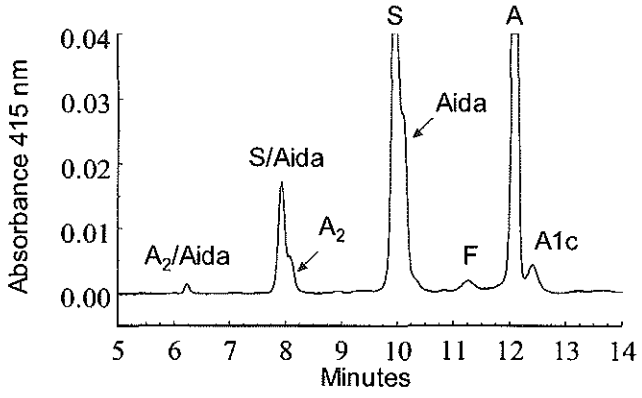

Figure 5-8 CE-based identification of uncommon hemoglobin (Hb) variants by cIEF.[14] Analysis of blood from a patient with Hb S/Aida trait detected the presence of seven different normal and abnormal structural Hb variants, some of which are not detectable by conventional electrophoresis because of a lack of sensitivity or inadequate resolution. The four abnormal variants include Hb S, Aida, S/Aida hybrid, and A_2/Aida. Identifying α-variants of Hb A_2 by cIEF helps discriminate between α- and β-globin gene mutations in samples containing unknown Hb variants. Glycated Hb A (HbA1c) is also apparent in the electropherogram.

MICROCHIP ELECTROPHORESIS

In the past decade, microchip electrophoresis has undergone substantial development, including integrated microchip designs, advanced detection systems, and new applications.[6,24,25,28] In the clinical diagnostic arena, the main analytes of interest for extrapolation to the microchip platform are proteins and DNA.

Among the attributes of microchip electrophoresis separations, the most notable is high speed—normally fourfold to tenfold faster than conventional CE and at least an order of magnitude faster than the slab gel format. Other advantages of microchips include simplicity, capabilities for chip integration of multiple functions, and certainly the potential for automation.

Instrumentation

Although similar in principle, the microchip system differs from its CE counterpart. For example, with the microchip approach, the separation channels, sample injection channels, reservoirs, sample preparation and/or precolumn or postcolumn reactors, and detectors and excitation sources can all be fabricated using photolithographic processes defined by the microelectronics industry, onto the surface of a microchip (see Chapter 10 for additional details on the manufacturing of such devices). Thus a truly multifunctional, "integrated" analytical device embedded in a single monolithic substrate is possible. The classic cross-t design of a single channel microchip involves a short (injection) channel that intersects a longer (separation) channel with a reservoir found at the ends of each of these as shown in Figure 5-9. The setup for LIF detection on a single channel microchip is shown in Figure 5-10.

Comparing volumes, the volume of the separation channel on a microchip is roughly an order of magnitude smaller (low nanoliters) than conventional capillary systems. With their decreased volume requirements (nanoliter to picoliters range), only the electrokinetic sample injection mode is used in microchips, because pressure injection is not easily controlled at these small volumes. In practice, an injection voltage of several hundred volts is applied across the sample and sample waste reservoirs to migrate the sample to the injection cross, which typically represents an injection volume of 50 to 100 pL. A separation voltage (1 to 4 kV) is then applied to the separation channel, which induces separation of the analyte zones before they reach the detection window downstream. It is important to note that, although the sample volume injected is ~100 pL, the actual sample volume necessary (for handling) is ~2 to 4 μL, depending on the reservoir size.

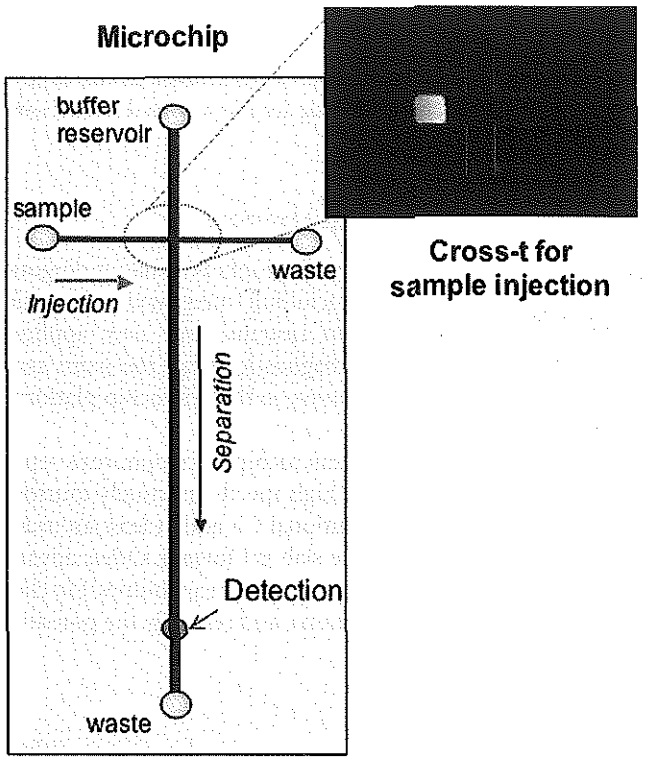

Figure 5-9 Simple cross-t microstructure design on chips used for electrophoretic separation.

Detection with a microchip is primarily through LIF, since this is easily implemented with the planar configuration of the microchip (Figure 5-10). Limits of detection for fluorescein-like fluors have been easily demonstrated at the 10^{-11} M level and pushed as low as 10^{-13} M—a mass detection limit of a few hundred molecules.[35] This allows for detection, for example, of polymerase chain reaction (PCR)-amplified DNA fragments at a level that competes with ^{32}P-autoradiography from Southern blots.[41] Typical microchip separation times are around 50 to 200 seconds.

Fabrication of Microchips

Other than the standard cross-t configurations, electrophoretic microchips are not currently commercially available and tend to be fabricated in the laboratories that use them. They can be constructed from glass (Pyrexlike or soda lime), silicon (as per microelectronic chips), or a variety of plastics, or cast from silicone-like materials (polydimethylsiloxane).[21] The first two of these constitute the vast majority of the electrophoretic devices described in the literature.

Etching the desired structures into a glass wafer surface is done with a buffered solution of hydrofluoric acid, thereby producing a series of U-shaped troughs [typically 70 μm (w) × 20 μm (d)] that interconnect appropriately. Smooth walls are typically achieved, but channels are U-shaped because of both downward and lateral etching by the etch solution. Consequently, features are often designed smaller than they have to be to allow for this type of spreading.

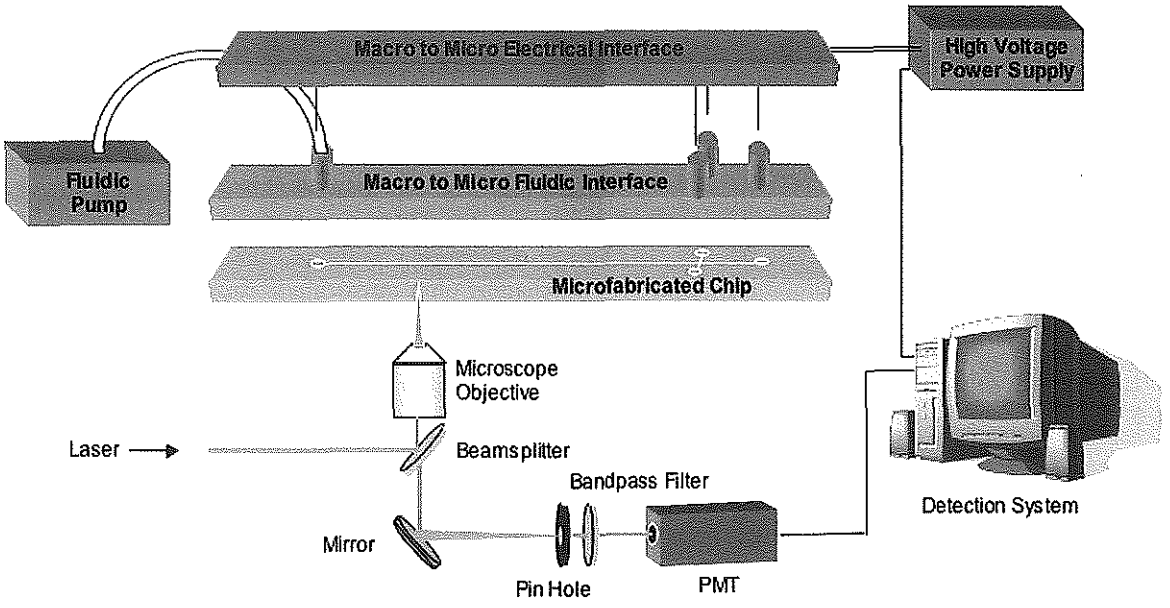

Figure 5-10 Detection system for LIF detection on microchips. Fluidic and electrical interfaces are indirectly fundamental to the detection system. The fluidic interface drives the preparation and flushing of the chip preseparation and postseparation, while the electrical interface drives the electrophoretic separation and controls the flow of fluid through the chip architecture via electrokinetic valving.

Following successful etching, the etched wafer is then bonded to a second piece of glass, into which reservoirs have been drilled, to enclose the chambers and channels of the device.

Molecular Diagnostics Using Microchips

As a result of the ease with which double-stranded (ds)DNA can be made to fluoresce via high affinity dsDNA fluorescent intercalators and the excellent detection sensitivity that results from LIF, DNA separations on microchips have developed more rapidl than protein separations. Consequently, capillary and microchip electrophoresis have emerged as alternatives to traditional slab gel electrophoresis for DNA analysis, this signified by the sequencing of the Human Genome using CE. A variety of polymers have been defined as "polymer networks" or "sieving matrices" effective for molecular sieving and size-based microchip DNA separations, many of which had been previously used in CE.

As described in the CE section, the chemical nature of the microchannel surface is equally important in DNA separations, where the electroosmotic flow has to be minimized or eliminated. For microchip-based electrophoretic DNA analysis, the chip surface must be passivated to reduce EOF. This can be accomplished by covalent modification with polymers like polyacrylamide (PA)[16]; however, the PCR samples must be desalted to achieve optimal resolution and acceptable longevity.[2,49] More attractive alternatives developed for CE involve polymers that have dual functionality, in that they both coat the microchannel surface and act as effective sieving polymers. The polydimethylacrylamide (PDMA) and the cellulosic polymers, hydroxyethyl cellulose and hydroxypropyl cellulose, have been shown to be very effective in this respect.[47]

There has been an almost exponential growth of literature with respect to the application of microchip electrophoresis to the molecular diagnosis of disease based on PCR-amplification of DNA (see Chapter 10).[23] Rudimentary microchip designs have been used to demonstrate the application of this platform in the most simplistic form—detecting the presence of a PCR product of diagnostic significance. This has been demonstrated with a number of applications including the detection of herpes simplex viral DNA in CSF for diagnosis of encephalitis, the detection of gene rearrangements correlative with lymphoproliferative dis-

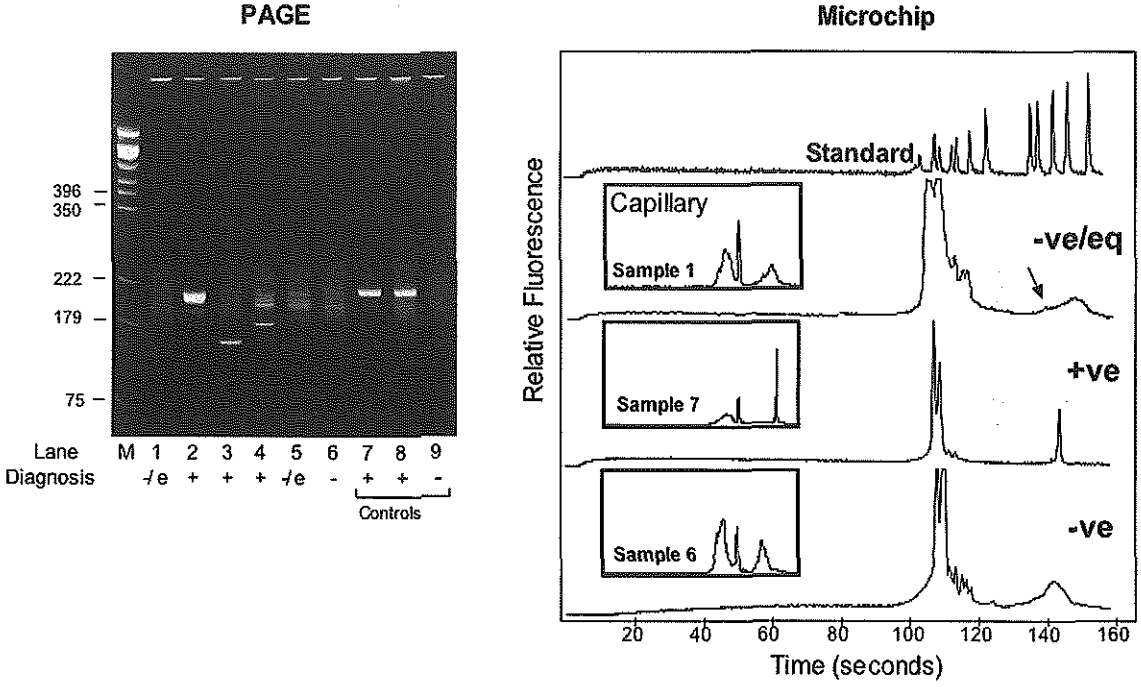

Figure 5-11 Electrophoretic detection of T-cell receptor γ-gene rearrangement products. Left—Slab gel electrophoresis of the amplified products resulting from PCR of nine patient samples. Right—capillary *(inset)* and microchip separations of select samples analyzed by gel electrophoresis on the left. The top profile results from separation of a DNA sizing standard. Sample 6 was consistent with a negative diagnosis for the gene rearrangement; sample 7 was positive as indicated by the dominant peak signifying clonality (peak at 142 seconds); sample 1 was deemed negative and/or equivocal based on the suspicious peak indicated by the arrow. Separation in both systems used hydroxyethylcellulose (HEC) as a polymeric sieving matrix and applied fields of 300 volts/cm and 275 volts/cm, respectively, for the capillary and microchip systems.[31]

orders, polymorphisms in the methylenetetrahydrofolate reductase (MTHFR) gene, the diagnosis of fragile X syndrome, the detection of tetranucleotide repeats associated with hypercholesterolemia, and the diagnosis of muscular dystrophy. More complicated DNA assays have been accomplished on electrophoretic microchips, including single-stranded conformation polymorphism (SSCP) or heteroduplex analysis for the detection of common mutations in the breast cancer susceptibility genes, BRCA1 and BRCA2.[23]

An example of microchip DNA separations applied to diagnosis of lymphoproliferative disorders is shown in Figure 5-11.[31] The high resolution (8%) acrylamide slab gel used for conventional analysis is given on the left for comparison. Because of the short separation length of the electrophoretic chamber (~4 cm) and the use of applied electrical fields comparable to those used in CE, separation on the microchip is complete in 160 seconds (in comparison with 8 hours for the slab gel).

More complicated microchip systems have been developed to address the high throughput requirements of molecular diagnostics laboratories (see Chapters 4, 10, and 37). For example, high throughput genetic typing has been performed on a 96-channel radial capillary array electrophoresis microplate with an unprecedented sample throughput of ~0.6 samples/s.[28,49] This has been extrapolated to a variety of other applications including the genotyping of the marker gene for diagnosis of hereditary hemochromatosis.[59]

CHAPTER 6

Chromatography*

M. David Ullman, Ph.D., and Carl A. Burtis, Ph.D.

On March 8, 1903, Mikhail Tswett presented a lecture at the meeting of the Biological Section of the Warsaw Society of Natural Sciences entitled "On a New Category of Adsorption Phenomena and Their Applications to Biochemical Analysis."[7] Later he reported that plant pigments were separated by differential adsorption on a column of calcium carbonate into a number of colored bands.[17] He originated the term "chromatography" to describe this process.

This chapter contains general discussions on basic concepts, separation mechanisms, resolution, specific types of chromatography, and qualitative and quantitative analysis.

BASIC CONCEPTS

Chromatography is a physical process whereby components (solutes) of a sample mixture are separated by their differential distribution between stationary and mobile phases.[6] During this process, the mobile phase carries the sample through a bed, layer, or column containing the stationary phase. As the mobile phase flows past the stationary phase, the solutes may (1) reside only on the stationary phase (no migration); (2) reside only in the mobile phase (migration with the mobile phase); and (3) distribute between the two phases (differential migration). Those solutes with higher affinity for the stationary phase reside in the stationary phase longer than those with less affinity, who therefore reside mostly in the mobile phase. Thus the lower affinity solutes travel faster and separate from solutes having greater affinities for the stationary phase. Strongly bound solutes subsequently are displaced from the stationary phase by changing the physical or chemical nature of the mobile phase. In this chapter, the term *chromatograph* is used as either a verb or a noun. As a verb, it means to separate by chromatography. As a noun, it refers to the assembly of components that are necessary to effect a chromatographic separation.

Planar and column are the two basic forms of chromatography (Figure 6-1). In planar chromatography, the stationary phase is coated on a sheet of paper (paper chromatography) or bound to a solid surface (thin-layer chromatography; TLC). For paper chromatography, the stationary phase is a layer of water or a polar solvent coated onto the paper fibers. In TLC, a thin layer of particles of a material such as silica gel is spread uniformly on a glass plate or a plastic sheet. When the thin layer consists of particles with small diameters (4.5 μm), the technique is known as *high-performance, thin-layer chromatography* (HPTLC).[18]

In column chromatography, the stationary phase may be a pure silica or polymer, or it may be coated onto, or chemically bonded to, support particles. The stationary phase may be "packed" into a tube, or it is coated onto the inner surface of the tube. The technique is termed either gas chromatography (GC) or liquid chromatography (LC), depending on whether the mobile phase is a gas or a liquid. Operationally the instrument used to perform a GC or LC separation is known as either a *gas* or *liquid chromatograph*. When the stationary phase in LC consists of small-diameter particles, the technique is high-performance liquid chromatography (HPLC). When a gas or liquid chromatograph is connected to a mass spectrometer, the combined or "hyphenated" techniques are gas chromatography/mass spectrometry (GC/MS) and liquid chromatography/mass spectrometry (LC/MS), respectively (see Chapter 7).

In analytical GC and LC, the mobile phase, or eluent, exits from the column and passes through a detector or series of detectors that produce a series of electronic signals that are plotted as a function of time, distance, or volume. The resulting graphical display is a chromatogram (Figure 6-2). The retention time or volume is the time or volume when a solute exits the column and passes through the detector. The data represented by the chromatogram are used to help identify

*The authors gratefully acknowledge the original contributions of Dr. Larry D. Bowers on which portions of this chapter are based.

and quantify the solute(s). Because eluting solutes are displayed graphically as a series of peaks, they are frequently referred to as *chromatographic peaks.* These peaks are described in terms of peak width, peak height, and peak area. In planar chromatography, the separated zones are detected by their natural colors or visualized through chemical modification that produces colored "spots" or "bands" that are used qualitatively to identify various analytes or quantify them.

SEPARATION MECHANISMS

Chromatographic separations are classified by the chemical or physical mechanisms used to separate the solutes. These include ion-exchange, partition, adsorption, affinity, and size-exclusion mechanisms. Predominantly, clinical applications use chromatographic separations based on ion-exchange and partition mechanisms.

Ion-Exchange Chromatography

As its name implies, ion-exchange chromatography is based on an exchange of ions between a charged stationary surface and mobile phase of the opposite charge (Figure 6-3). Depending on the conditions, solutes are either cations (positively charged) or anions (negatively charged). They are separated depending on the differences in their ionic charge or the magnitude of their ionic charges. Operationally, the particle surfaces of a plastic resin or silica serve as the stationary phase to which functional groups with fixed cationic or anionic charges are bound. To maintain electrochemical neutrality, an exchangeable ion, termed the *counterion,* is found in close proximity to the fixed charge and solute ions in the mobile phase exchange with the counterions. The solute ions then are eluted selectively by variation of the mobile phase pH, ionic strength, or both.

Cation-exchange particles contain covalently bound, negatively charged functional groups and are used to separate or "exchange" cationic solutes. Examples include strongly acidic

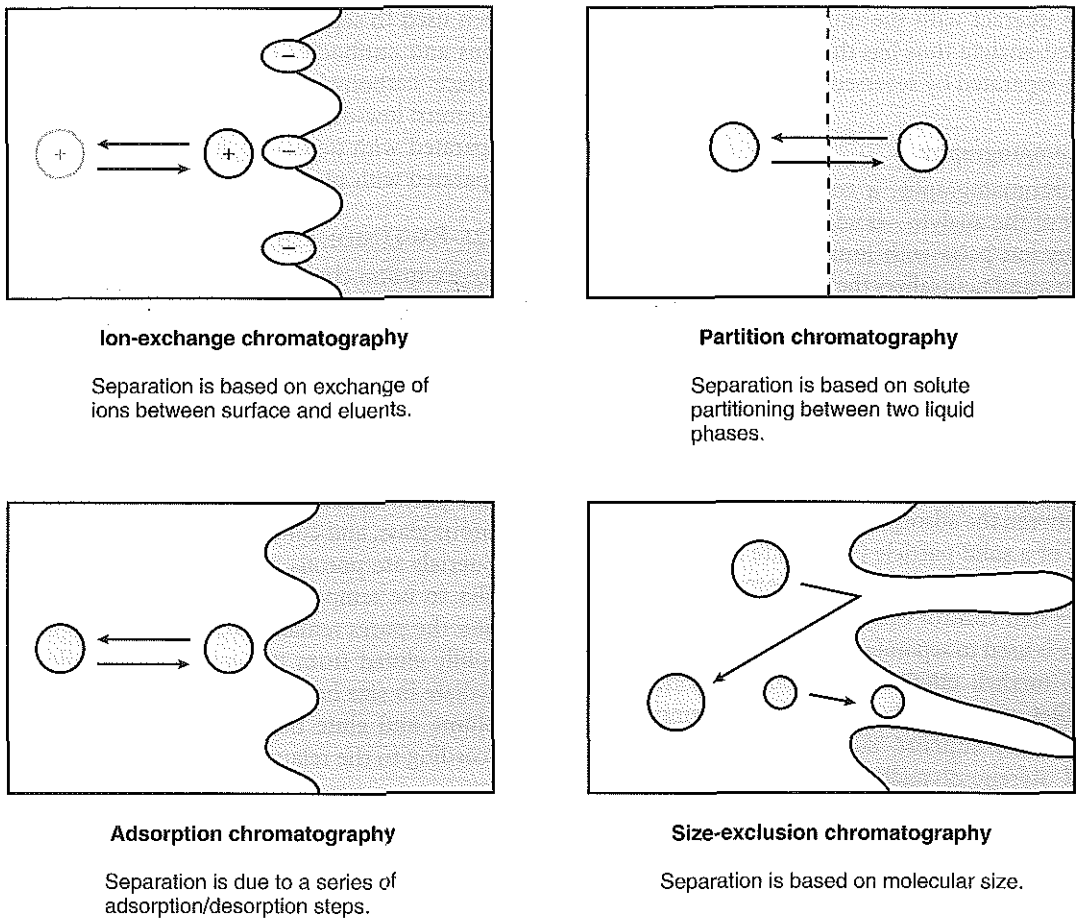

Figure 6-3 Examples of separation mechanisms used in chromatography. *(Courtesy James K. Hardy, Akron, Ohio [http://ull.chemistry.uakron.edu/].)*

groups—such as sulfonate ions, or weakly acidic groups—such as carboxylate ions or carboxymethyl (CM), phosphate (P), sulfomethyl (SM), sulfoethyl (SE), or sulfopropyl (SP) groups. Anion-exchange packings are used to separate anionic solutes. They have strongly basic quaternary amines with positive charges. Examples include triethylaminoethyl groups or weakly basic groups, such as aminoethyl (AE), diethylaminoethyl (DEAE), guanidoethyl (GE), and epichlorohydrin-triethanolamine (ECTEOLA) groups.

Ion-exchange chromatography has many clinical applications, including the separation of amino acids, peptides, proteins, nucleotides, oligonucleotides, and nucleic acids. Another important application of ion-exchange chromatography is the separation and removal of inorganic ions from aqueous mixtures. Thus most water purification units used to prepare deionized water for the laboratory contain "mixed-bed" columns of cation and anion resins (see Chapter 1).

Partition Chromatography

The differential distribution of solutes between two immiscible liquids is the basis for separation by partition chromatography (see Figure 6-3). Operationally, one of the immiscible liquids serves as the stationary phase. To prepare this phase, a thin film of the liquid is adsorbed or chemically bonded onto the surface of support particles or onto the inner wall of a capillary column. Separation is based on differences in the relative solubility of solute molecules between the stationary and mobile phases.

Partition chromatography is categorized as either GLC or liquid-liquid chromatography (LLC). LLC is further categorized as either normal phase or reversed phase. For normal-phase LLC a polar liquid is used as the stationary phase, and a relatively nonpolar solvent or solvent mixture is used as the mobile phase. In reversed-phase partition chromatography, the stationary phase is nonpolar, and the mobile phase is relatively polar.[13]

Ion-suppression and ion-pair chromatography are two forms of reversed-phase chromatography used to separate ionic solutes.

Ion-Suppression Chromatography

With ion-suppression chromatography, the ionic character of a weakly acidic or basic analyte is neutralized or "suppressed" through modification of the mobile phase pH. By neutralizing its ionic group, the solute is less polar and

better able to interact with the nonpolar stationary phase. The suppressed analyte thus has the properties of a neutral species and is separated by reversed-phase chromatography.

Ion-Pair Chromatography

In ion-pair chromatography, a counter ion—opposite in charge to that of the analyte—is added to the mobile phase, where it forms ion pairs with ionic analytes, displaces the usual base pairs, and neutralizes the analyte ion(s). These ion pairs then are separated by reversed-phase chromatography. In practice, ion-pair chromatography is particularly useful for separations of therapeutic drugs and their metabolites.

Adsorption Chromatography

The basis of separation by adsorption chromatography is the differences between the adsorption and desorption of solutes at the surface of a solid particle (see Figure 6-3). Electrostatic, hydrogen-bonding, and dispersive interactions are the physical forces that control this type of chromatography. In GC, this mode is used to separate low molecular weight compounds (e.g., methyl, ethyl, and isopropyl alcohols) and compounds that are normally gases at room temperature. It uses particles of support, such as "molecular sieves," alumina, and styrene-divinylbenzene copolymers. In LC, three types of adsorbents are generally used—nonpolar, acid polar, and basic polar. The nonpolar adsorbents include charcoal and polystyrene-divinylbenzene. The main acidic polar adsorbent is silica gel, the surface silanol (SiOH) groups of which adsorb basic substances. Alumina is the main basic adsorbent for retaining acidic substances. Florisil has also been used as a basic adsorbent when catalytic decomposition of the analyte is observed with alumina.

Affinity Chromatography

In affinity chromatography the unique and specific biological interaction of the analyte and ligand is used for the separation (Figure 6-4). The specificity resulting from enzyme-substrate, hormone-receptor, or antigen-antibody interactions has been used in this type of chromatography.

The stationary phase in affinity chromatography is prepared by immobilizing a *ligand* on particles of a support either directly or via a *spacer*. A variety of chromatographic supports have been used, including agarose, cross-linked dextrans, polyacrylamide, cellulose, polystyrene, and controlled-pore glass. Adjustments of pH and ionic strength are required to achieve optimal binding of the analyte to the ligand. If the interaction between analyte and ligand is specific, the analyte may be displaced in a single step by the addition of a substrate or an inhibitor, or by a pH change, an ionic strength change, or addition of a hydrogen bond–breaking agent—such as guanine hydrochloride, urea, or sulfite. The latter group of compounds is also known as *chaotropic agents*.

The power of affinity chromatography lies in its selectivity. In the clinical laboratory, affinity chromatography has been used to separate and prepare larger quantities of proteins and antibodies for further study. Cells with different surface carbohydrate moieties are separated with lectin columns; low-density and very low-density lipoproteins are separated with heparin columns; glycated hemoglobins are separated with phenyl boronate columns.

Size-Exclusion Chromatography

Size-exclusion chromatography, also known as *gel-filtration, gel-permeation, steric-exclusion, molecular-exclusion,* or *molecular-sieve chromatography,* separates solutes on the basis of their molecular sizes (Figure 6-5; see Fig. 6-3). Molecular shape and hydration are also factors in the process.

A variety of materials are used as stationary phases for size-exclusion chromatography, including cross-linked dextran, polyacrylamide, agarose, polystyrene-divinylbenzene, porous glass, and combinations of the above. Beads of these materials are porous with pore sizes that allow small molecules to be temporarily entrapped. Molecules too large to enter the pores remain entirely in the mobile phase and are rapidly eluted from the column. Molecules that are intermediate in size have access to various fractions of the pore volume and elute between the large and small molecules according to the relation:

$$V_r = V_0 + KV_i \qquad (1)$$

where V_r is the retention volume, V_0 is the void volume between the particles, K is the fraction of the pore volume accessible to the molecule, and V_i is the volume within the support particles. The retention is limited to one column volume; therefore resolution is limited. For this reason, steric exclusion is used more for preparative than for analytical purposes.

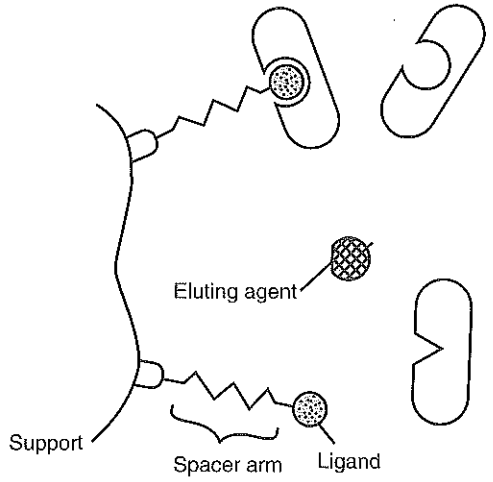

Figure 6-4 Principle of affinity chromatography. The analyte (enzyme, antibody, antigen, tissue receptor, etc.) binds to the support-bound ligand. Subsequently, it is eluted with a general eluent (such as a chaotropic agent), pH change, or biospecific eluent (such as an inhibitor or substrate).

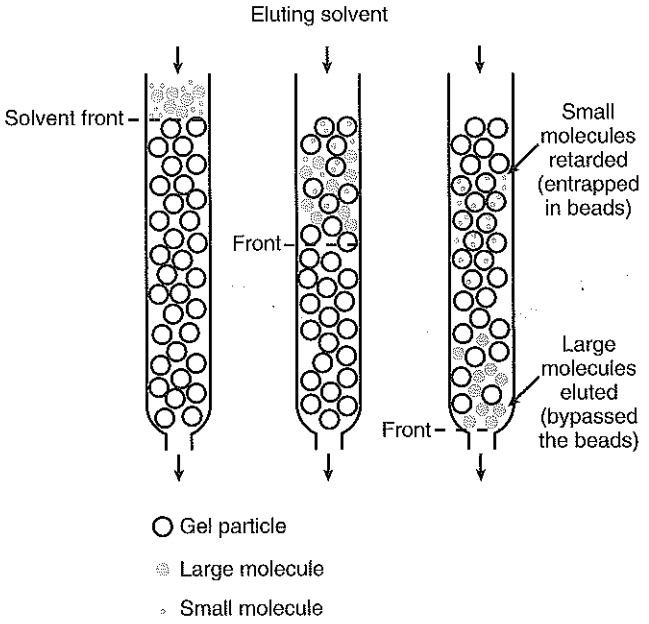

Figure 6-5 Schematic representation of gel-filtration column chromatography. *(Modified from Bennett TP: Graphic biochemistry, vol 1. Chemistry of biological molecules. New York: Macmillan, 1968.)*

RESOLUTION

Resolution (R_s) is a measure of a successful chromatographic separation and requires that two peaks have different elution times for the peak centers and sufficiently narrow bandwidth to eliminate or minimize overlap (Figure 6-6).[3] It is expressed mathematically as follows:

$$R_s = \frac{V_r(B) - V_r(A)}{\left[\frac{w(A) + w(B)}{2}\right]} \quad (2)$$

where

$V_r(A)$ = retention volume for solute A
$V_r(B)$ = retention volume for solute B
$w(A)$ = bandwidth (units of volume) measured at base for solute A
$w(B)$ = bandwidths (units of volume) measured at base for solute B

Resolution also is expressed in terms of time, with $V_r(A)$ and $V_r(B)$ being replaced with retention times $t_r(A)$ and $t_r(B)$, and $w(A)$ and $w(B)$ being expressed in units of time.

Incomplete separation occurs when the calculated value for R_s is less than 0.8, whereas baseline separation is obtained when R_s is greater than 1.25 (Figure 6-7). As demonstrated in Figure 6-8, when R_s is unacceptable for a given separation,

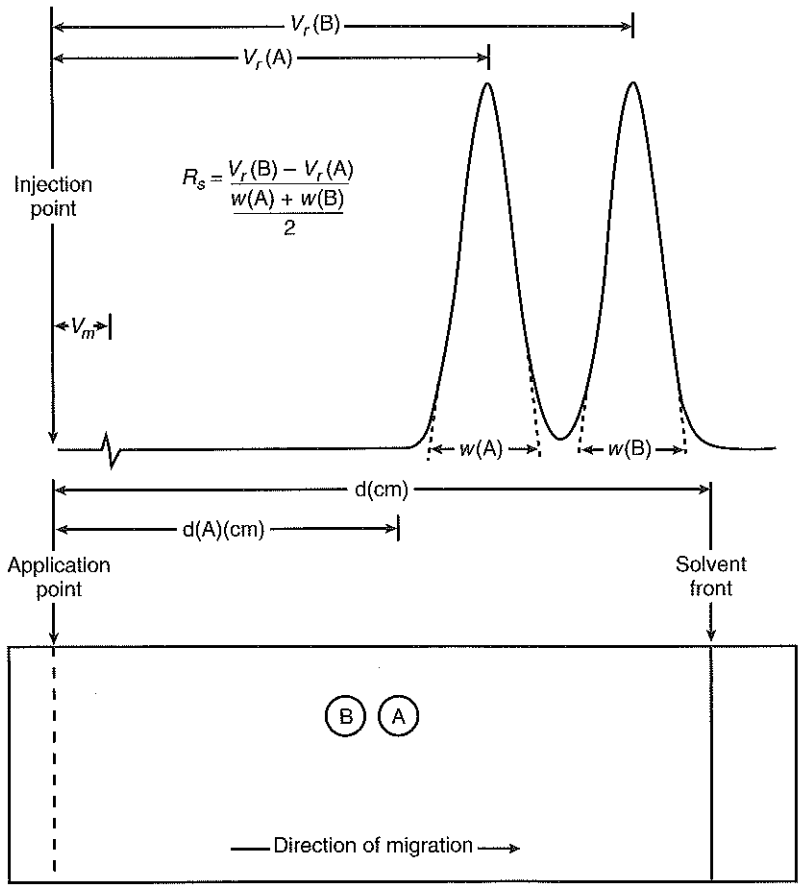

Figure 6-6 Schematic diagram of a chromatogram obtained from a column and open-bed chromatograph (planar). In open-bed chromatography *(bottom)*, strongly retained compounds (B) move more slowly than less strongly retained compounds. In column chromatography *(top)*, compound B is eluted later than compound A, again because of stronger retention. R_s, Resolution; $V_r(A)$, retention volume for solute A; $V_r(B)$, retention volume for solute B; $w(A)$, bandwidth (units of volume) measured at base for solute A; $w(B)$, bandwidth (units of volume) measured at base for solute B; V_m, volume between injector and detectors; $d(A)$, distance traveled by solute A; *A*, solute A; *B*, solute B.

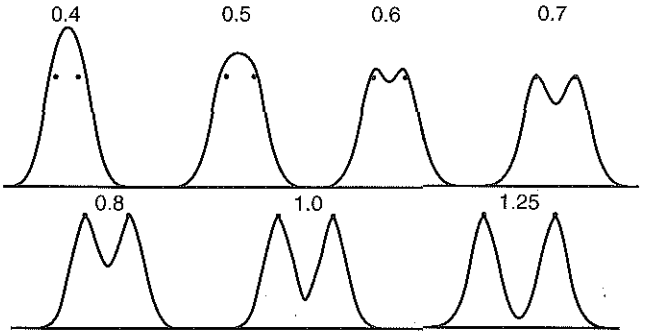

Figure 6-7 Separation of chromatographic peaks present in a 1:1 ratio as a function of resolution (R_s). *(From Snyder LR: A rapid approach to selecting the best experimental conditions for high-speed liquid column chromatography. Part I. Estimating initial sample resolution required by a given problem. J Chrom Sci 1972; 10:202.)*

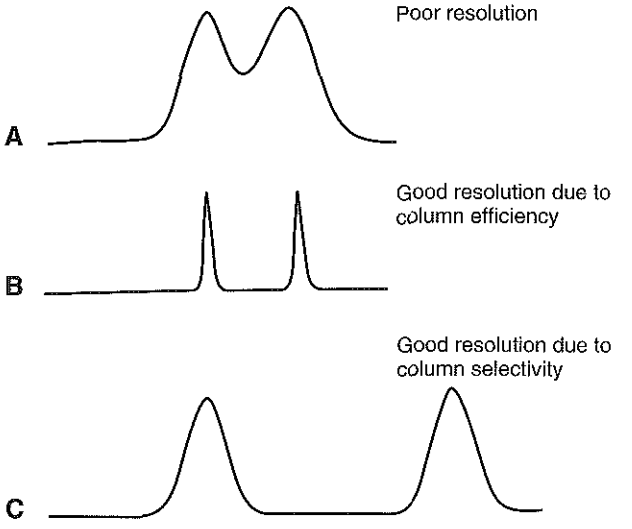

Figure 6-8 Effect of selectivity and efficiency on chromatographic resolution. **A,** Poor resolution. **B,** Good resolution because of column efficiency. **C,** Good resolution because of column selectivity. *(From Johnson EL, Stevenson R: Basic liquid chromatography, Palo Alto, Calif, Varian Associates, 1978.)*

it is improved through a change in (1) the column retention factor (k'), (2) column efficiency (N), or (3) column selectivity (α). The retention factor describes the distribution of solutes between stationary and mobile phases. Column efficiency accounts for the ease of physical interaction between solute molecules and column-packing material. Selectivity characterizes the specific chemical affinity between solute molecules and column packing. Thus by rearranging equation (1) and expressing the parameters in terms of retention, efficiency, and selectivity, resolution also is expressed as:

$$R_s = \left(\frac{k'}{k'+1}\right) \times \frac{\sqrt{N}}{4} \times \left(\frac{\alpha - 1}{\alpha}\right) \tag{3}$$

where k' = retention or capacity factor (a thermodynamic term), N = number of theoretical plates (a kinetic term representing column efficiency), and α = selectivity factor (a thermodynamic term).

These factors are varied to affect the degree of resolution of a given separation. However, a practical approach to improve resolution is to adjust first the retention factor to an acceptable value and then improve the efficiency. Finally, if required, the selectivity is changed.

Retention Factor (k')

"The retention factor is a measure of the time the sample component resides in the stationary phase relative to the time it resides in the mobile phase."[8] Mathematically, it is the ratio of the adjusted retention volume (v_r) or retention time (t_r) to the void volume (v_0) or hold-up time (t_0) (the time for unretained components to elute from the column).

$$k' = \frac{V_r - V_0}{V_0} = \frac{t_r - t_0}{t_0} \tag{4}$$

The distribution of a solute between the stationary and mobile phases affects the rate at which it migrates through a column or bed. The resultant distribution constant (K_D) is defined as the ratio between the concentrations of the solute molecules in the stationary phase (C_s) relative to those in the mobile phase (C_m):

$$K_D = \frac{C_s}{C_m} \tag{5}$$

Substituting these concentrations with the numbers of molecules (N_s and N_m) per unit volume (V_s and V_m) and rearranging terms, equation (9) becomes:

$$K_D = \left[\frac{N_s}{N_m}\right] \times \left[\frac{V_m}{V_s}\right] = k' \times \beta \tag{6}$$

The ratios N_s/N_m and V_m/V_s are defined as the retention factor, k', and the phase ratio, β, respectively. The retention factor is also a measure of the time a solute molecule spends in the stationary phase relative to the time it spends in the mobile phase and thus is related to the retention time of the solute:

$$k' = \frac{t_r - t_0}{t_0} \tag{7}$$

where t_r is the elution or retention time of retained solute, and t_0 is the elution time of the unretained solutes.

The magnitude of k' is a function of the solute chemical and physical properties, the stationary and mobiles phases, and the column temperature. Also, solute retention is increased by increasing the amount of the stationary phase relative to that of the mobile phase. A large k' is indicative of a slowly moving solute band, which improves the resolution between it and those of other solutes but also results in its broadening. In practice, optimum values of k' are between 2 and 6, although values between 1 and 10 can be used.

In some circumstances, when (1) 10 or more compounds in a sample are of interest, (2) analytes vary widely in their

chemical characteristics, or (3) *isocratic* conditions (constant mobile phase composition and column conditions) are employed, a range of k' values may be required to achieve the desired separation or separations. When k' values are high, an extremely long time is required for separation, and detection limits are compromised because of band spreading. This situation (high k' values, long analysis time, and decreased detection limit) is known as the *general elution problem*. In practice, this problem is solved by changing peak retention as a function of time. In TLC, this is accomplished by two-dimensional development; in GC, by programmed changes in column temperature; and in LC, by altering the composition of the mobile phase as a function of time *(gradient elution)*.

The retention factor is also used to predict the position in time of a particular compound under the selected conditions of separation. For example, the k' can be used to compare solute retention from one chromatographic system to another because—given the same mobile phase, stationary phase, and stationary phase particle size—it will not differ with flow rate or column diameter and length.

In planar chromatography, all separation activity must occur within the distance traveled by the mobile phase. In TLC, a solute's migration is expressed by its R_f value, which is calculated from the relation:

$$R_f = \frac{\text{distance from application point to solute center}}{\text{distance from application point to solvent front}} \quad (8)$$

Therefore the greater the solute affinity for the stationary phase, the smaller the R_f value. For comparison R_f and k' are related as follows:

$$R_f = \frac{1}{1 + k'} \quad (9)$$

Efficiency (N)

Ideally, as a solute moves through a bed or column of the stationary phase, it migrates as a very narrow band. In practice, however, the band broadens as it passes through the column. This is primarily a result of (1) nonuniform flow of the mobile phase as it moves past the stationary phase particles, (2) variability in the physical dimensions of the particles, and (3) diffusion. Using column chromatography as an example, band spreading implies that if identical molecules start as a narrow band in a small volume at the top of the column, they will appear at the column outlet in a larger volume and broader band. Two of the major contributions to band spreading are *eddy diffusion* and *mass transfer* phenomena. Eddy diffusion results when solute molecules traverse different flow paths through the bed of the stationary phase. Some flow paths may be linear, and others are circuitous. Further, the flow paths may be narrower or broader so that molecules in the broader paths travel faster than those in the narrower. Solute molecules distribute randomly into these paths, and those following the more direct and/or wider paths will emerge from the end of the column sooner than those in the more circuitous and/or narrower paths. Thus the solute band is broadened.

Mass transfer processes are composed of (1) mobile phase mass transfer, (2) stagnant mobile phase mass transfer, and (3) stationary phase mass transfer. *Mobile phase mass transfer* is caused by the different mobile phase flow rates for different parts of a single flow path between two stationary phase particles. The mobile phase close to one of the particles moves slowly, and the center of the flow stream (farthest from particles) moves fastest. *Stagnant mobile phase mass transfer* occurs when solute molecules become temporarily delayed in stagnant pools of mobile phase located in pores of the support particles. Here, the solute molecules must reenter the flowing mobile phase through diffusional movement. *Stationary phase mass transfer* occurs when solute molecules diffuse into and within the stationary phase. These molecules must be extricated from the particles and the stagnant pool by diffusional movement. Mass transfer processes are strongly dependent on the characteristics (e.g., particle size, pore size, and particle shape) of the column packing.

Because the equilibria (thermodynamics) are identical for a given solute, band broadening is related to flow dynamics (kinetics). In chromatographic terminology, a bed or column of stationary phase that minimizes the broadening of solute bands is considered "efficient." In column chromatography, a very efficient column is characterized by the appearance of narrow peaks in the chromatogram (see Figure 6-8). Column efficiency is expressed as N, the number of "*theoretical plates.*" Mathematically, N is defined as:

$$N = \left[\frac{V_r(\text{A})}{s(\text{A})}\right]^2 \quad (10)$$

where $V_r(\text{A})$ and $s(\text{A})$ are the retention volume and standard deviation of the peak volume for solute A (see Figure 6-6). The standard deviation of a graphical display, however, is difficult to measure. A more easily measured quantity is used to determine the number of theoretical plates. Tangents are drawn to the ascending and descending curves of the gaussian peak. The distance between the points where the tangents intersect the chromatographic baseline is four standard deviations. Alternatively the width of a gaussian peak at one half its height corresponds to 2.354 standard deviations, and therefore:

$$s(A) = \frac{w_{1/2}(\text{A})}{2.354} \quad (11)$$

Substituting the latter relationship into equation (10), the number of theoretical plates is determined by measuring the width of a peak at half height, $w_{1/2}(\text{A})$, and using the relationship:

$$N = 5.54\left[\frac{V_r(\text{A})}{w_{1/2}(\text{A})}\right]^2 \quad (12)$$

Efficiency is often expressed as the number of theoretical plates per unit length of column (N/L) or the reciprocal

(L/N) of this relationship, which is called the plate height *(H)* or the *height equivalent of a theoretical plate (HETP)*. Thus:

$$H = \frac{L}{N} \tag{13}$$

where L is the column length. These expressions correspond to "imaginary" physical entities widely used to characterize the relationship of band spreading to column characteristics in chromatographic systems.

In theory a theoretical plate is equivalent to the length of a column necessary to allow one equilibration of the solute to occur between the stationary and the mobile phases. To increase the efficiency of a column, the number of theoretical plates is increased. In practice, this can be accomplished by increasing the length of the column. It should be remembered, however, that, as shown in equation (3), resolution is proportional to the square root of column efficiency. Therefore doubling the column length would only result in a 40% increase in resolution.

Other factors that affect efficiency are characteristics of the stationary support particles, mobile phase viscosity, column temperature, and noncolumn contributions. In general a decrease in (1) mobile phase flow rate, (2) average particle size of the stationary phase, (3) particle size distribution, and (4) volume of sample will increase efficiency. Increases in column length, temperature, and sample viscosity also increase efficiency.

For GC the relationship between the plate height and flow velocity is given by the van Deemter equation:

$$H = \mathrm{A} + \frac{\mathrm{B}}{\mathrm{v}} = \mathrm{Cv} \tag{14}$$

where v is the flow velocity of the mobile phase, and A, B, and C are constants related to the mechanistic components of dispersion. Eddy diffusion, that is independent of flow velocity, contributes to the A term. The B term arises from diffusion of the analytes along the longitudinal axis of the column and is important only at low-flow velocities. The C term includes contributions from radial diffusion in the mobile phase and diffusion in the stationary phase. Because basic differences in the rates of these processes exist in gases and liquids, the relationship for LC is given by the Knox equation:

$$H = \mathrm{Av}^{1/3} + \frac{\mathrm{B}}{\mathrm{v}} + \mathrm{Cv} \tag{15}$$

For both GC and LC, the efficiency of a chromatographic system is optimal at intermediate flow velocities. Optimal performance is usually not obtained in practice because of the emphasis on separation speed, which requires the use of greater than optimal flow rates. Theoretical considerations of the thermodynamic and kinetic aspects of chromatography led to the development of HPLC and capillary GC, both of which possess the speed necessary for clinical analyses.

The efficiency of any chromatographic system will be reduced if noncolumn contributions to band spreading are not properly minimized. For example, precolumn and postcolumn tubing, connectors, column fittings, and detector cell must all be of minimum volume.

Selectivity (α)

The *selectivity factor* (α) is a measure of the relative separation between the band centers of two solutes. It is expressed as the ratio of the retention factors of the second eluting solute k'(B) and the first eluting solute k'(A) of the two solutes A and B:

$$\alpha = \frac{k'(\mathrm{B})}{k'(\mathrm{A})} = \frac{[t_r(\mathrm{B}) - t_0]}{[t_r(\mathrm{A}) - t_0]} \tag{16}$$

where t_r (A) and t_r (B) are the elution times of solutes A and B, respectively. By convention the solute with the larger k' is placed in the numerator. Thus the value of α is always 1 or greater. To develop a chromatographic separation, the chosen mechanism should afford a large α value. After the separation mechanism has been chosen, alteration in the magnitude of α is achieved by changing the composition of the mobile phase (e.g., pH, ionic strength, and solvent polarity in LC and HPLC), the column temperature in GC and HPLC, the chemical and physical nature of the column packing or stationary phase, or chemical modification of the solute. When two solutes have identical values for k', α is equal to 1.0, and the solutes are not separated. It is technically feasible, but difficult, to separate two compounds having a α of 1.01; however, it is reasonably easy to separate them if α is 1.05 and easy to separate them if α is 1.10 or greater.

PLANAR CHROMATOGRAPHY

Planar chromatography was developed in the 1950s.[16] With it, solutes are separated on a planar surface of the stationary phase. Paper and TLC are subclassifications of planar chromatography (see Figure 6-1). In paper chromatography, the stationary phase is a layer of water or a polar solvent coated onto the paper fibers.

In TLC a thin layer of sorbent, such as silica gel (usually only 0.2 mm thick), is spread uniformly on a glass plate, plastic sheet, or aluminum foil. Prepared plates are available commercially that are coated with a variety of sorbents (e.g., silica gel, microcellulose, alumina, or cross-linked dextran). The sample is added as a small spot or band near an edge of the plate. The plate then is placed in a closed glass container or tank with the lower edge in, and the sample band just above, the mobile phase (Figure 6-9). The mobile phase then migrates up the plate by capillary action. After the mobile phase travels a desired distance, the plate is removed from the tank and dried. Additional separation is achieved if the plate is developed in a second direction. In addition to this "ascending" technique, thin-layer plates also are developed in a radial mode. After the plate is dry, the separated com-

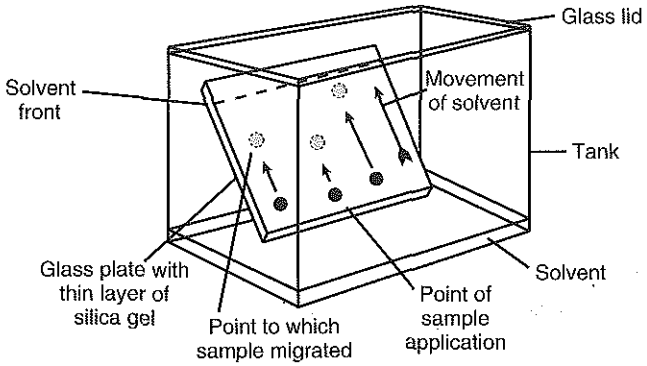

Figure 6-9 Illustration of TLC. The solvent moves up the thin layer of adsorbent by capillary action. *TLC*, Thin-layer chromatography. *(Modified from Bennett TP: Graphic Biochemistry, vol 1. Chemistry of biological molecules, New York: Macmillan, 1968.)*

ponents are located and identified by a variety of procedures, such as ultraviolet (UV) illumination (fluorescence), spraying with specific, color-generating reagents, or autoradiography. Provided the detection method is nondestructive, the appropriate sorbent region can be scraped from the plate and extracted to recover the solute for further study or analysis.

Silica gel continues to be a widely used sorbent for TLC. Other sorbents include inorganic and organic sorbents, such as alumina (neutral and acidic), magnesium silicate, diatomaceous earth (kieselguhr), cellulose, polyamide, and ion-exchange resins.[11] In the 1990s, a range of alkyl-bonded silica TLC plates became commercially available including C_{18}, C_{12}, C_8, C_2, aminopropyl, diphenyl, and cyanopropyl bonded plates.[8] Plates coated with a chiral complexing agent are also available and used for the separation of amino acid enantiomers and similar compounds. The bonded silica plates are used in reversed-phase TLC, which has proven useful for the chromatography of polar compounds. The use of small-diameter, stationary phase particles led to the development of HPTLC. The HPTLC separations are more efficient and reproducible because particles of small diameters are used. Inadequate wetting and solvent evaporation must be controlled carefully. Laser-coded TLC plates are available in which each plate is identified individually to prevent recording and archiving errors.

In practice, the majority of TLC separations are qualitative or semiquantitative (visual comparison) in nature. However, modern computer-controlled densitometers are now available that scan sample and calibrator chromatograms in tracks on HPTLC plates and provide quantitative capabilities.[15] Clinically relevant analytes that have been measured by TLC include amino acids, bile acids, carbohydrates, drugs, lipids, glycolipids, phospholipids, porphyrins, prostaglandins, steroid hormones, purines, pyrimidines, derivatives of nucleic acid, and urinary organic acids. The advantages of TLC include simplicity, rapidity, versatility, ability to process a large number of samples in minimal time, and low cost in terms of reagent and equipment.[11]

COLUMN CHROMATOGRAPHY

In column chromatography, the stationary phase is coated onto or chemically bonded to support particles that are then "packed" into a tube, or the stationary phase is coated onto the inner surface of the tube. GC and LC are subclassifications of column chromatography (see Figure 6-1).

GAS CHROMATOGRAPHY

GC was developed by James and Martin in 1952[9] to separate fatty acids. With it a gaseous mobile phase is used to pass a mixture of volatile solutes through a column containing the stationary phase. The mobile phase is typically an inert gas, such as nitrogen, helium, hydrogen, or argon, referred to as the *carrier gas*. Solute separation is based on the relative differences in the solutes' vapor pressures and interactions with the stationary phase. Thus a more volatile solute elutes from the column before a less volatile one. In addition, a solute that selectively interacts with the stationary phase elutes from the column after one with a lesser degree of interaction. The column effluent carries separated solutes to the detector in the order of their elution. Solutes are identified qualitatively by their similar retention times. Peak size (area or height) is proportional to the amount of the solute detected and is used to quantify it.

Gas-solid chromatography (GSC) and gas-liquid partition chromatography (GLC) are variations of GC. In GSC separations occur primarily by differences in absorption at the solid phase surface. In GLC a nonvolatile liquid is coated or chemically bonded onto particles of column packing or directly onto the wall of a capillary column. Separation occurs primarily by differences in solute partitioning between the gaseous mobile phase and the liquid stationary phase.

Instrumentation

The components of a basic gas chromatograph are illustrated in Figure 6-10.

Column Technology

The function of the chromatographic column is to separate the solutes. The main types of columns are packed and capillary. Packed columns are filled with support particles that are used uncoated (GSC) or have been coated or chemically bonded with the stationary phase (GLC). They vary from 1 to 4 mm in internal diameter (ID), from 1 m or more in length, and are fabricated from tubes of glass or stainless steel. Although narrow columns are more efficient, wider columns have increased sample capacities. Fast GC is a type of GC in which high-speed separations are achieved using short lengths of conventional columns. Longer columns are more efficient but require increased carrier gas pressures.

Capillary columns, also known as *wall-coated open tubular columns,* are fabricated by coating the inner wall of a fused-silica tube with a thin film of liquid phase. They vary from 0.1 to 0.5 mm in ID and from 10 to 150 m in length. The ultrapure fused silica capillary tubing is very fragile. To physically strengthen the tubing a thin outside coating of polyimide or aluminum is added; this improves column durability. These modified capillary columns have the structural strength and flexibility necessary to withstand coiling and placement in ovens. Capillary columns are very efficient but have low sample capacities.

In addition to the packed and capillary columns, progress has been made in the development of micro GC columns on silicon chips. These microdevices have great potential for high-speed GC, a miniature GC, and eventually even a pocket GC[5] (see Chapter 10 for a discussion on nanotechnology).

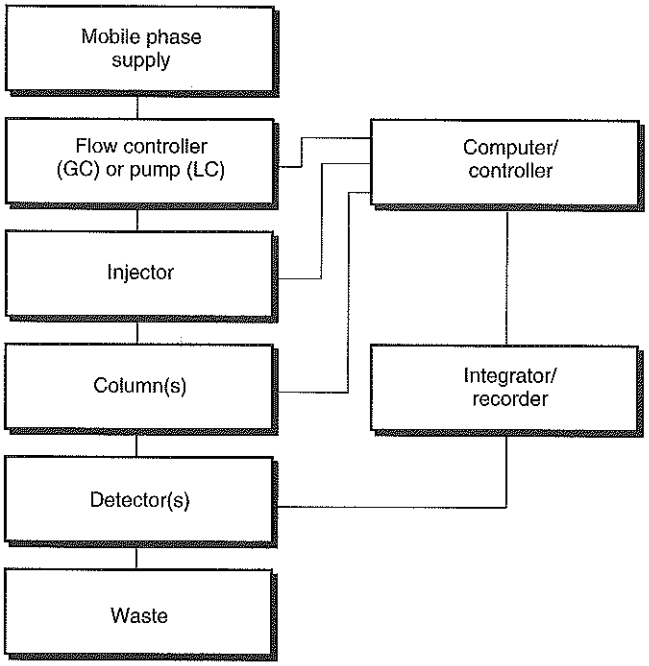

Figure 6-10 Schematic diagram of a gas or liquid chromatograph. *GC,* Gas chromatography; *LC,* liquid chromatography.

A variety of compounds have been used as the stationary phase in GLC. These include methyl silicone polymers, substituted silicone polymers, and silicone polyesters (Table 6-1). These materials are coated or chemically bonded onto the surface of the support particles or onto the walls of the column. Although more expensive, bonded materials are preferable because of their stability.

Carrier Gas Supply and Flow Control

The function of the carrier gas supply and flow control is to provide carrier gas to the chromatographic column and to regulate its flow through the system. Operationally a constant flow of carrier gas is required for column efficiency and reproducible elution times. Systems that provide constant flow rates vary from simple mechanical devices to sophisticated electronic ones. For example, a simple system consisting of a tank of compressed gas, a needle valve to adjust flow, a flow meter, and a pressure gauge is sufficient for many applications. More demanding temperature-programmed operation (discussed later) requires a more sophisticated differential flow controller, such as an electronic pressure control system programmed to regulate the carrier gas flow rate and pressure during a chromatographic run. Such a controller is operated in either a constant-flow or a constant-pressure mode. In the constant-flow mode, the pressure required to maintain a constant flow independent of carrier gas viscosity is calculated. A pressure transducer then measures and maintains the inlet pressure required for the constant flow.

The magnitude of the carrier gas flow rate depends on the type of column. For example, packed columns require a flow rate from 10 to 60 mL/min. Flow rates for capillary columns are much lower (1 to 2 mL/min), and the maintenance of a constant flow rate is even more critical for the efficient operation of these columns.

A number of gases are used as carrier gases, depending on the column and detector. Hydrogen and helium are the carrier gases of choice with capillary columns. Only high-purity hydrogen and helium should be used, however, because carrier-gas impurities (1) harm the column, (2) decrease the performance of some detectors, and (3) adversely affect quantification in trace analysis. For packed columns, the most frequently used carrier gas is nitrogen,

TABLE 6-1 Stationary Phases Commonly Used in Gas Chromatography for Clinical Separations

Composition	Polarity	Similar Phases	Applications
100% dimethyl-polysiloxane	Nonpolar	OV-1, SE-30	Drugs, amino acid derivatives
5% diphenyl—95% dimethyl-polysiloxane	Nonpolar	OV-101, SP-2100	Drugs
50% diphenyl—50% dimethyl-polysiloxane	Intermediate	OV-17	Drugs, steroids, glycols
50% cyanopropylmethyl—50% phenylmethyl-polysiloxane	Intermediate	OV-225	Fatty acid methyl esters, carbohydrate derivatives
Polyethylene glycol	Polar	Carbowax 20 M	Acids, alcohols, glycols, ketones

which is used with flame ionization (FID), electron capture (ECD), or thermal conductivity (TCD) detectors. Helium is used with FIDs and TCDs, and nitrogen-argon-methane mixtures are used with the ECD. Carrier gases should be pure and dry, and the tubing used to connect the gas source to the GC should be uncontaminated. Molecular sieve beds and specialized inline traps have been used to remove or reduce the moisture, hydrocarbon, or oxygen content of the carrier gas.[4]

Injector

The function of an injector is to introduce an aliquot of the sample to be analyzed into the column; this begins the chromatographic process and has to be done with a minimal disruption of the gas flow into the column. In most clinical GC methods, samples are dissolved in nonaqueous liquids introduced into the column via an inline injector. With packed columns, a glass microsyringe is used to inject a 1- to 10-μL aliquot of the dissolved sample through a septum, which serves as the interface between the injector and the chromatographic system. In practice, the syringe needle is inserted through the injector septum and into a heating region. The volatile analytes and the solvent are then "flash-vaporized" and swept into the column by the carrier gas. To ensure rapid and complete solute volatilization, the temperature of the injector is maintained at 30° to 50 °C higher than the column temperature.

Common problems with GC analysis include septum leaks and adsorption of components from the sample onto the septum during injection. In addition, because the septum is heated, decomposition products often form and "bleed" into the column. This results in spurious peaks, termed "ghost" peaks, appearing in the chromatogram. Septum bleed is greater at higher injection-port temperatures. To minimize this problem, a Teflon-coated, low-bleed septum is used. The inner surface of the septum is purged continuously with the carrier gas that is vented before it passes into the column. This approach is especially effective, and most commercial injectors are equipped with continuous-purge capabilities. The septum is a consumable component of the gas chromatograph and should be replaced at least once every 100 injections.

Because of the low sample capacities and carrier-gas flow rates used with capillary columns, split and splitless injection techniques are used to introduce samples into the columns. In the split mode (Figure 6-11), only a small portion of the vaporized sample enters the column, whereas in the splitless mode most of the sample enters the column (Figure 6-12). Operationally the split flow mode is used for samples that contain relatively high concentrations of the target analyte(s); the splitless mode is used for samples that contain relatively low levels of the target analyte(s).

Temperature-programmable injection ports are available and are used in either the split or splitless mode. The sample is injected at a temperature slightly higher than the boiling point of the solvent. Most of the sample components condense on glass or fused silica wool in the injector insert, while the solvent is removed. The injector is then rapidly heated at rates of up to 100 °C/min. The rapid heating vaporizes the analytes, which then move into the column. Very rapid heating is advantageous in that thermally labile compounds are only exposed to high temperatures for a short time. Separation of solvent removal and analyte vaporization allows injection of sample volumes up to hundreds of microliters. This obviously improves analyte detection when the sample matrix is not the limiting factor.

Temperature Control

Operationally, both packed and capillary columns require careful control of the column, injector, and detector temperatures. Control of the column temperature is achieved when the column is placed in an oven or when the column is heated directly by resistive heating.[10] Injector and detector temperatures usually are controlled by electrical resistance

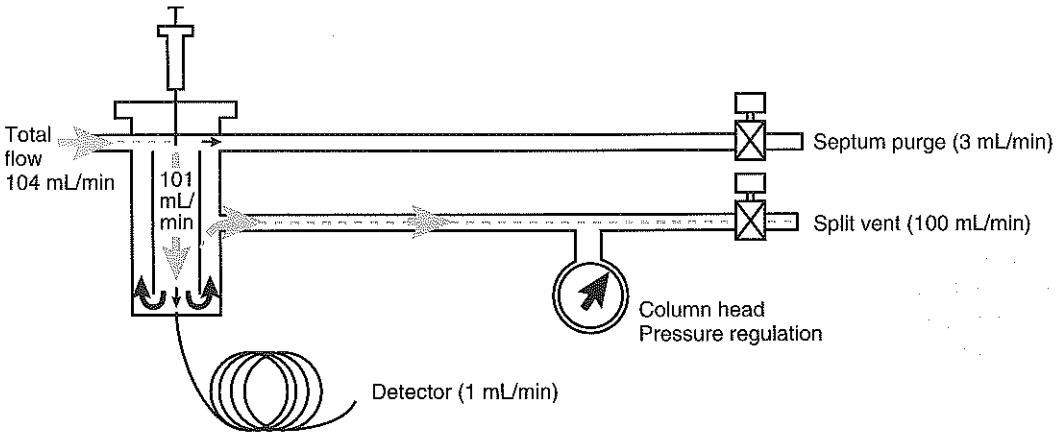

Figure 6-11 Flow diagram of a GC inlet system for split injection. The head pressure and total flow are adjusted to achieve a desired flow rate in the column and a fractional split between the column and the split vent. *GC*, Gas chromatography.

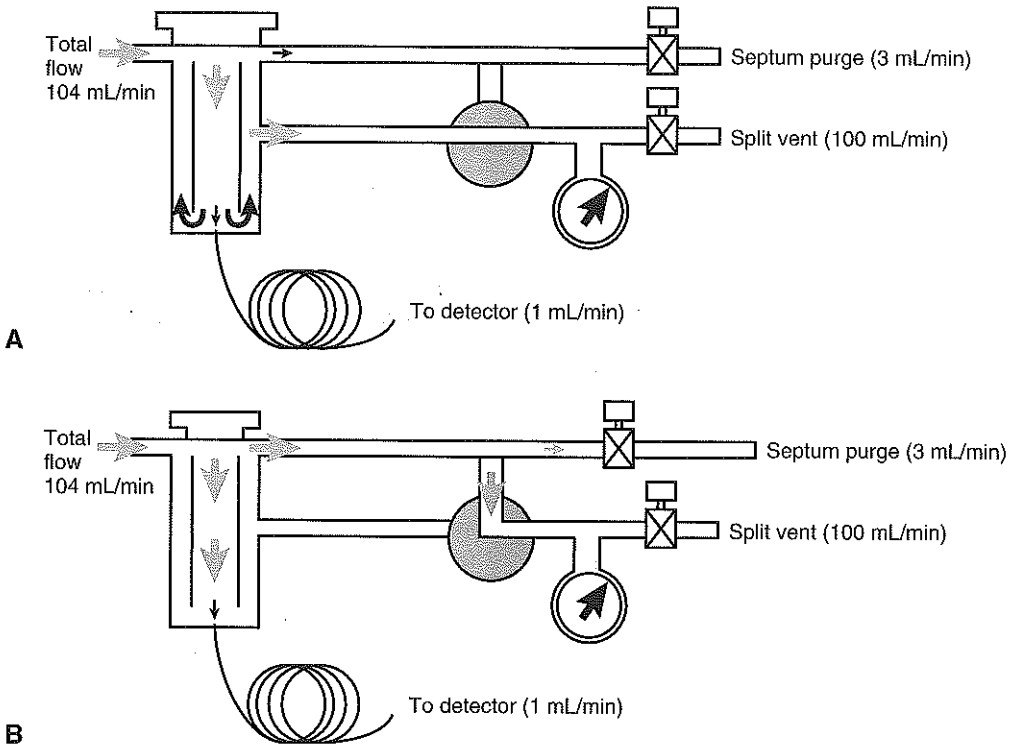

Figure 6-12 Flow diagram of a GC inlet system for splitless injection. Initially the system has most of the flow through the injection liner, with the majority of it directed to the split vent **(A)**. When an injection is made, flow is directed through the septum purge line, and all material in the injection liner is transferred into the column **(B)**. After 50 to 80 seconds, the flow is again directed through the liner **(A)** to purge any material remaining in the liner through the split vent; meanwhile, a constant flow is maintained through the column. *GC*, Gas chromatography.

heating. Depending on the application, the column temperature is maintained at either a constant preset level (isothermal operation) during the chromatographic run or varied as a function of time (temperature-programmed or temperature-gradient operation).

In practice, temperature-programmed column heating is used for most clinical applications. With temperature programming, the solutes having the lower boiling points elute first, followed by those having higher boiling points. Consequently a complex mixture of solutes with a wide range of boiling points is separated into sharp, distinct chromatographic peaks in less time than with isothermal operation. The temperature is programmed and controlled by a computer and its resident software.

In capillary gas chromatographs, the accurate and precise control of column and injector temperatures is required to obtain optimal performance and accurate results. Temperature control of the column is especially important, particularly in qualitative applications in which the retention times or volumes of eluting peaks are compared with those of authentic standards for identification. A change of only 1 °C causes a 5% change in retention time. In addition, instability of the column temperature adversely affects retention time or volume comparability among instruments or with values in the literature. Temperature gradients in the oven and rapid temperature programming rates also causes variable analyte retention.

The thermal stability of the stationary phase is also important. Because each stationary phase has a range of thermal stability, it is important to control column temperature within the specified range. For the nonpolar phases, the temperature limit is determined by the stability of the polyimide coating. The introduction of aluminum clad columns notably broadens the useable temperature range. Oxidation at higher temperatures limits the operating temperature of intermediate to polar phases.

Before any column is used, it must be "thermally conditioned" by heating the column at various temperatures for different lengths of time. This removes volatile contaminants, including residual monomers, in the polymeric stationary phase. In addition, thermal conditioning of used columns removes accumulated nonvolatile contaminants that cause unstable baselines. To condition a column thermally, it is disconnected from the detector and purged for at

TABLE 6-2 Examples of Detectors Used in Gas Chromatographs

Type of Detector	Principle of Operation	Selectivity	Limit of Detection	Comments
Thermal conductance (TCD)	Measures thermal conductivity change in carrier gas on elution of compounds	Universal	<400 pg propane/mL He	
Flame ionization (FID)	CHNO + heat → $CHNO^+ + e^-$; electrons collected for detection	Hydrocarbon	10 to 100 pg CHO	
Thermionic selective (TSD; NPD)	Alkali bead selectively ionizes N- or P-containing compounds	N, P	0.4 to 10 pg N 0.1 to 1.0 pg P	
Electron capture (ECD)	$e^- + R + N_2 \rightarrow Re^- + N_2 + e^-$; excess electrons collected; concentration inversely related	Electronegative groups	0.05 to 1.0 pg Cl^- containing compounds	
Mass spectrometer (MS)	$e^- + ABC \rightarrow A^+ + BC$; monitor mass-to-charge ratio by either scanning or single-ion monitoring (SIM)	Universal (tunable)	1 ng scan 10 pg SIM	Provides structural confirmation; ion ratios constant in SIM
Photoionization (PID)	CHNO + photon → $CHNO^+ + e^-$; detect electron	Hydrocarbon	1 to 10 pg CHO	May be improvement on FID
Electrolytic conductivity (Hall)	Postcolumn reaction detector for selective detection of halogen-, S-, or N-containing compounds	Halogen-, S-, and N-containing compounds	0.1 to 1.0 pg Cl 2.0 pg S 4.0 pg N	
Flame photometric (FPD)	P- and S-containing hydrocarbons emit light when burned in FID-type flame; emitted light detected	P- and S-containing compounds	0.9 pg CHP 20 pg CHS	
Fourier transform infrared (FTIR)	Infrared wavelength light absorbed by the compound of interest	Universal (tunable)	1 ng strong infrared absorber	Scanned for structural information or absorbance-measured for quantitation

NPD, Nitrogen-phosphorus detector.

least 5 minutes with pure carrier gas. It is then heated to above 50 °C. The column temperature is then cycled through a normal temperature program three or four times. Alternatively the column can be maintained at the maximum operating temperature for 12 to 24 hours. The thermal conditioning of columns at lower temperatures prolongs the life of the column, but longer conditioning times are required to achieve baseline stability.

Detectors

The purpose of an online detector is to sense and measure the separated analytes as they elute from the column. A variety of sensitive detectors are used with gas chromatographs. These include universal units that detect most analytes and extremely selective devices that detect only specific ones (Table 6-2). Examples include FID, thermionic selective (TSD), ECD, photoionization (PIDs), and TCD. Many other devices have been used as GC detectors, and it has become a common practice to place two or more detectors in a series to enhance analytical specificity and sensitivity.[5] Different types of mass spectrometers are also used as detectors for gas chromatographs (see Chapter 7).

Flame Ionization Detector. The FID is the most commonly used detector for clinical analysis (Figure 6-13). Its advantages include simplicity, reliability, versatility, sensitivity, and ease of operation. During operation the column effluent is mixed with hydrogen and air, and the eluting compounds are burned by a flame. About one molecule in 10,000 produces an organic cation and releases an electron, which is detected by a collector electrode positioned above the

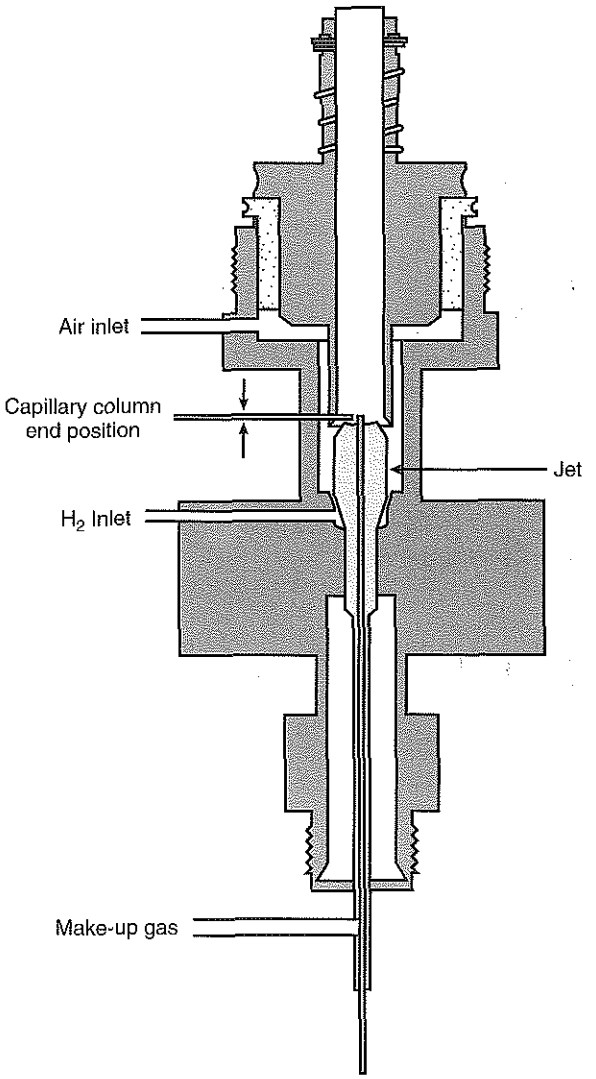

Figure 6-13 Schematic diagram of an FID equipped with make-up gas. *FID,* Flame ionization detector. *(Modified from Hyver KJ: High resolution gas chromatography, 3rd edition, Palo Alto Calif: Hewlitt Packard, 1989.)*

flame. The magnitude of the generated current is related to the mass of carbon material delivered to the detector; after measurement, it is used for detection and quantification of the eluting solutes.

Thermionic Selective Detector. The TSD, also known as the *nitrogen-phosphorus detector (NPD),* is a modification of the FID in which an alkali bead is heated electrically in the area above the jet. In the presence of alkali atoms in the flame, nitrogen-containing compounds give a 15 times greater, and phosphorus-containing compounds a 300 times greater, response.

Electron Capture Detector. The operating principle of the ECD is based on the reaction between electronegative compounds and thermal electrons. The electrons are normally provided from a radioactive source, such as ^{63}Ni or ^{3}H housed in the detector. A collector electrode is pulsed to collect "excess" electrons. This is called the *standing current.* If electronegative species are not present in the detector cell, the nitrogen or argon/methane (95/5) sweep gas removes most of the electrons from the cell. When a compound capable of capturing an electron passes through the cell, some electrons are removed, and a decrease in the standing current is observed. The use of nitrogen or argon/methane is important, because these gases reduce the energy of the electrons via collisions and thus improve the ability of the compounds to "capture" them. It is also important that the gasses be very pure and dry because oxygen and water foul the detector. In some detector designs, the collection pulse rate is varied to maintain a constant amount of current. Then the pulses are counted and used to determine the concentration of electronegative species passing through the cell. The ECD is a concentration-dependent detector. The presence of electronegative constituents, such as fluorine, chlorine, bromine, and iodine, increases the ECD's response. Because not all compounds contain these functional groups, derivatization with reagents containing polychlorinated or polyfluorinated groups to increase detector response is a common practice.

Photoionization Detector. The PID is a variant of the FID. With the PID, however, the energy for ionization is provided by an intense UV lamp rather than by a flame. The PID has a lower limit of detection than the FID because it produces less baseline "noise."

Thermal Conductivity Detector. The TCD is based on the principle that addition of a compound to a gas alters the thermal conductance of the gas. It is used often with capillary GC. The operating principle of the ECD is based on the reaction between electronegative compounds, such as fluorine, chlorine, bromine, and iodine, and thermal electrons. Because not all compounds contain these functional groups, derivatization with reagents containing polychlorinated or polyfluorinated moieties is a common practice used with an ECD.

Different types of mass spectrometers are also used as detectors for gas chromatographs (see Chapter 7).

Computer/Controller

For many years, various digital devices provided both system control and data processing functions for chromatographs (Figure 6-14). The incorporation of computer technology into chromatographic instrumentation resulted in cost-effective, easy-to-operate automated systems with impressive analytical performance. As a process controller, the computer regulates various parameters, such as (1) mobile phase composition and flow rate, (2) column back pressure, (3) column and detector temperatures, (4) sample injection, detector selection and operation, and (5) the various timing steps that command the operation of the system. For data processing, the computer monitors signals generated by the system's detectors and commands the acquisition and storage of data at specified time intervals. The area, or height, of each chromatographic peak is determined from the stored

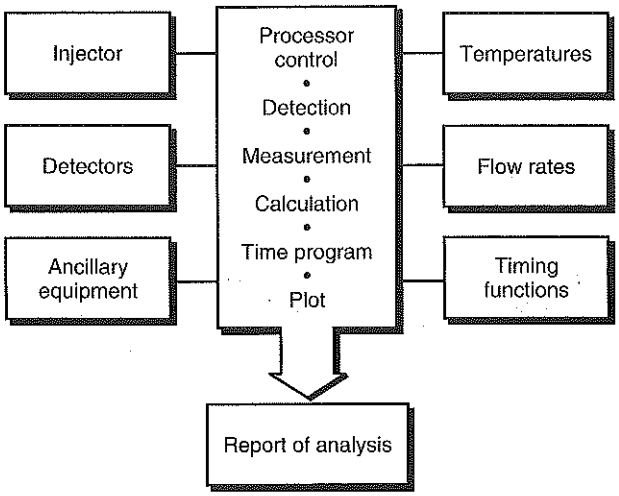

Figure 6-14 Functions of computers in gas and liquid chromatographs.

data and used to compute the analyte concentration represented by each peak. Available algorithms for this computation include those based on calibration curves or conversion factors from internal or external calibration. If desired a complete report can be prepared and printed for each chromatographic run. Alternatively, data are stored to be recalled and reprocessed, with different integration parameters, when desired.

Practical Considerations

Several techniques affect the practical application of GC in the clinical laboratory, including those used to extract and derivatize samples for analysis.

Sample Extraction

For GC analysis, extraction of the analyte from the sample is often necessary. For example, to extract barbiturates from serum, the serum first is acidified to convert the barbiturates into a form soluble in an organic solvent, such as dichloromethane. A volume of this solvent then is shaken vigorously with the acidified serum. When the aqueous and organic layers separate, most of the barbiturates are present in the organic phase, and many interferences, such as proteins, remain in the aqueous phase. Solvent extraction is also frequently used to increase the concentration of an analyte before chromatographic analysis.

Sample Derivatization

Many clinically relevant compounds are nonvolatile, and therefore they are difficult to separate by GC. However, chemical modification or derivatization of such compounds increases their volatility for GC analysis. Chemical reactions used to form these nonpolar derivatives include acylation, silylation, esterification, and oximation. In addition to enhancing solute volatility, derivatization is also used to enhance the specificity and sensitivity of particular separations. For example, the use of a chiral reagent to derivatize amphetamine improves specificity and allows the separation of the D- and L-isomers on a standard GC column. Enhanced ability to detect is also achieved via preparation of pentafluoropropyl derivatives for use with the ECD.

Liquid Chromatography

In 1941 Martin and Synge[14] developed *partition chromatography* (also known as *liquid-liquid chromatography*). They demonstrated that monoamino acids and monocarboxylic acids were separated more efficiently by a short column of water-coated silica gel than by any solvent extraction apparatus.

In the late 1960s, emphasis was placed in developing LC as a complementary technique to GLC. In the early 1970s, the evolution and application of chromatographic theory, coupled with the technical improvements and advancements made in instrumentation and separation media, resulted in the development of HPLC and later *capillary gas and liquid chromatography*.[2]

Separation by LC is based on the distribution of the solutes between a liquid mobile phase and a stationary phase. When particles of small diameter are used as the stationary-phase support, the technique is HPLC. Because column efficiency is inversely related to the column packing particle size and pressure drop is related to the square of the particle diameter, relatively high pressures are required to pump liquids through efficient HPLC columns. Consequently the technique has also been referred to as *high-pressure liquid chromatography.* In the clinical laboratory, HPLC is the most widely used form of LC. It has been used for assaying or monitoring many clinically relevant analytes, including amino acids, peptides, proteins, carbohydrates, lipids, nucleic acids and related compounds, vitamins, hormones, metabolites, and drugs such as antiarrhythmics, antibiotics, antiepileptics, analgesics, bronchial smooth muscle relaxants, and tricyclic antidepressants.

Instrumentation

The basic components of a liquid chromatograph are shown in Figure 6-10.[12] With these components, various types of HPLC systems are assembled. These range from single-pump, single-solvent units to versatile, automated systems.

Column Technology

Advances in column technology have improved the selectivity, stability, and reproducibility of LC analytical columns. For example, analytical columns are packed with a variety of stationary phases, providing enormous versatility in the separation process. This section describes (1) column dimensions, (2) particulate column packings, (3) monolithic column packings, and (4) the use of guard columns.

Column Dimensions. Modern column technology has produced columns in different dimensions with the tendency toward smaller internal volumes prevailing for analytical, especially hyphenated, techniques (see Chapter 7).

For use in the clinical laboratory, most analytical HPLC are fabricated from tubes made of 316 stainless steel that have IDs ranging from 0.3 mm to 5 mm and lengths from 50 mm to 250 mm (Table 6-3). Column end fittings, which have zero dead volume and frits to retain the support particles, are used to connect the column to the injector on the inlet end and the detector on the outlet end. Generally, lower detection limits are achieved with columns having smaller IDs. These smaller ID columns are manufactured from narrow bore (approximately 2.1 mm ID) and microbore (approximately 1.0 mm ID) tubes. In addition to providing improved efficiency, columns with smaller IDs use decreased volumes of mobile phase. For example, a 2-mm-ID column requires about fivefold less solvent than a 4.6-mm-ID column (see Table 6-3).

Capillary columns used in LC are constructed by coating the inner wall of a fused-silica tube with a thin film of liquid phase. These columns vary from 0.1 to 0.5 mm in ID and from 10 to 50 cm in length.

Particulate Column Packings. Particulate packings have particle diameters ranging from 1.8 to 10 μm. The packings provide efficient columns with acceptable operating back pressures. Since the back pressure is inversely proportional to the square of the particle diameter, very small mean particle diameter packings require shorter columns to prevent prohibitive back pressures. These types of columns are useful with HPLC/mass spectrometry (HPLC/MS) techniques because of the low solvent volumes required to effect adequate separations. Irregularly shaped or spherical packings that provide lower back pressures are also available.

Types of particulate packings include bonded, polymeric, chiral, and restricted access materials.

Bonded Phase Packings. In this type of packing, the stationary phase is bonded chemically to the surface of silica particles through a silica ester or silicone polymeric linkage. Bonded phase packings (1) are mechanically and chemically stable, (2) have long lifetimes, and (3) provide excellent chromatographic performance. Bonded phase packings are available for ion-exchange and both normal-phase and reversed-phase chromatography. In normal-phase HPLC, the functional groups of the stationary phase are polar relative to those of the mobile phase, which usually consists of nonpolar solvents, such as hexane. Examples of polar functional groups for normal-phase HPLC packings are silanol, amino, and nitrile groups. Reversed-phase HPLC requires a nonpolar stationary phase. The most popular reversed-phase packing is the C18 type, in which octadecylsilane molecules are bonded to silica particles. A column with octadecyl packing is often called an *ODS column* (ODS, octadecyl silica). Reversed-phase column retention and selectivity characteristics are altered via attachment of other groups, such as octyl, phenyl, or cyanopropyl, to the silica.

Polymeric Packings. Graphitized carbon or mixed copolymers are used as polymeric packing (e.g., polystyrene-divinylbenzene) or further derivatized with ion-exchange or C4, C8, or C18 functional groups. Columns filled with these packings feature levels of performance comparable to those of silica-based columns and are stable from pH 2 to 13.

Chiral Packings. Chiral packings are used to separate enantiomers, which are mirror-image forms of the same compound. In the clinical laboratory this type of packing is used to separate and quantify drug enantiomers.

Restricted Access Packings. With this type of packing, the outer surfaces of the support particles are protected by a hydrophilic network. Smaller solutes, such as drugs, pass through the network into the pores, which are coated with hydrophobic stationary phase. Large protein molecules are denied access to the inner core and pass through the column. Columns filled with restricted access packing allow the direct injection of biological samples with high protein concentrations, which bypasses sample preparation and improves analytical accuracy.

In addition to the packings described above, particulate packings (1) with both reversed phase and normal-phase characteristics, (2) compatible with high temperatures (up to 100 °C), or (3) having large pore sizes (e.g., 300 Å) are available commercially.

Monolithic Particulate Column Packings. In recent years, monolithic column packings have been introduced that have some advantages over the classical particulate packings. Monolithic column packings with silica-based or polymer-based monolithic rods have bimodal pore structures with large pores (approximately 2-μm diameter), which create high pore density, and smaller ones (approximately 13-nm diameter), which create a large internal surface area. The high surface area provides good separation, and the high porosity minimizes flow back pressure that allows high flow rates. Thus analysis time is greatly reduced. Further, existing silica-based and polymer-based particle separations are transferred with minimal investment in method development. Also, the lower back pressure appears to provide highly reproducible column characteristics because many of the factors that degrade particulate columns are eliminated (e.g., packing down and channeling). The monolithic rods are encased in inert polytetrafluoroethylene (PTFE) tubing and housed in stainless steel

TABLE 6-3 Types of Columns Used in HPLC

Column Terminology	Column ID (mm)	Optimum Flow Volume
Standard	4.6	1.25 mL/min
	4.0	1.0 mL/min
Narrow bore	3.0	0.6 mL/min
	2.0	200 μL/min
Microbore/capillary	1.0	50 μL/min
	0.5	12 μL/min
	0.3	4 μL/min

HPLC, High-performance liquid chromatography; *ID*, internal diameter.

tubes. The inert tubing eliminates void volumes at the stainless steel tube monolithic rod interface, thus improving resolution. Two additional advantages of these columns are that they can be used with mobile phase flow gradients (e.g., increasing flow rate at the end of a separation), and several columns can be coupled in a series to improve resolution with little increase in flow back pressure. Also, capillary monolithic columns are available.

Guard Columns. To prevent an analytical column from irreversibly adsorbing proteins, with a subsequent reduction in both resolution and column life, a guard column is placed between the injector and analytical column. A guard column is packed with the same or similar stationary phase as the analytical column. It collects particulate matter and any strongly retained components from the sample and thus conserves the life of the analytical column. After a predetermined number of separations, a guard column is routinely replaced.

Solvent Reservoir

Solvents used as the mobile phase are contained in solvent reservoirs. In their simplest forms, the reservoirs are glass bottles or flasks into which "feed lines" to the pump are inserted. To remove particles from solvents, inline filters are placed on the inlets of the feed lines. Sophisticated mobile phase handling systems available commercially contain specially designed bottles with internal, conically shaped bottoms that allow small solvent volumes to be used. These handling systems also feature three or four valve caps that permit the filtration, storage, and delivery of solvents, and a stopcock for vacuum degassing.

Pump

Both constant pressure and constant displacement pumps are used in liquid chromatographs. Constant displacement pumps, however, are used more widely. During its operation the constant displacement pump withdraws (aspirates) the mobile phase from the solvent reservoir and delivers a reproducibly constant flow of it through the chromatographic system. Several different types of pumps are used for this purpose, including the syringe pump single-piston, rapid-refill reciprocating pump; diaphragm pump; and the most widely used dual-piston reciprocating pump.

A dual-piston reciprocating pump uses an asymmetrical cam to drive two pistons into and from two pumping chambers (Figure 6-15). The reciprocating action of the pump, however, creates "pump pulsations" that result from changes in the flow rate. The changes affect the output signals of some detectors, thereby increasing baseline noise that influences the detection limit of the system. Thus most reciprocating pumps use mechanical or electronic pulse dampers and/or multiple heads that operate out of phase to deliver a mobile phase continuously. Another technique uses a significantly more rapid refill stroke than delivery stroke. Reciprocating pumps operate at up to 10,000 psi and generate flow rates from 0.01 mL/min to 20 mL/min or greater, depending on pump head size and configuration.

The HPLC pump is operated in either an isocratic or gradient mode (Figure 6-16). In the isocratic mode, the mobile phase composition remains constant throughout the chromatographic run. This mode is usually used for simpler separations and separations of those compounds with similar structures and/or retention times. An isocratic mobile phase is a single solvent (e.g., methanol) or a prepared mixture of several solvents (e.g., methanol, acetonitrile, and water) delivered from a single solvent reservoir. Alternatively a multisolvent mobile phase can be metered and proportioned from two or more reservoirs. Most HPLC separations are performed under isocratic conditions.

Gradient elution is used for more complex separations.[1] In this mode, mobile phase composition is changed during the run in either a stepwise or continuous fashion. Many different techniques are used to generate gradient profiles. In one technique, two or more pumps are used in parallel. A variety of gradient profiles are generated through programming of the output of each pump. Alternatively the

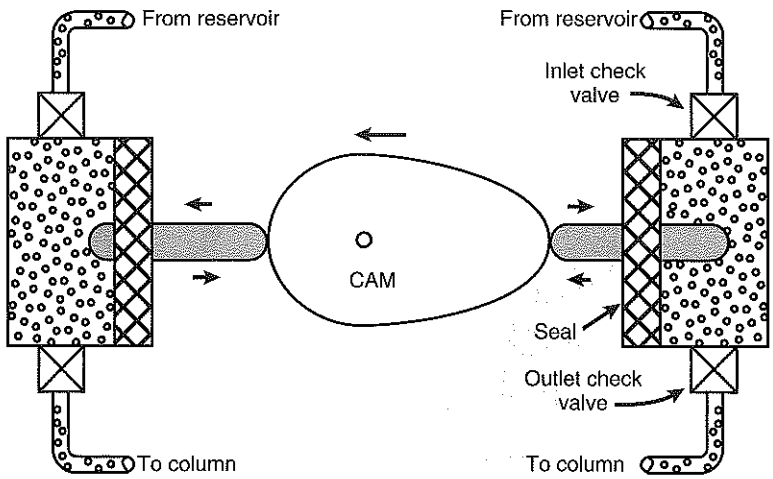

Figure 6-15 Cross-sectional view of a dual-piston reciprocating pump. *(From Walker JQ, Jackson MT Jr, Maynard JB: Chromatographic systems: Maintenance and troubleshooting, 2nd edition, New York: Academic Press, 1977.)*

mobile phase is proportioned on the inlet side of a single pump. For example, up to four solvent reservoirs may be connected via proportioning valves to the inlet check valve of a single pump. The composition of the mobile phase is then varied through programming of the time during which solvent is delivered through each of the proportioning valves.

Injector

To initiate an LC separation, an aliquot of sample (e.g., 0.2 to 50 μL) is first introduced into the column via an injector. The most widely used type of injector is the fixed-loop injector (Figure 6-17). In the fill position, an aliquot of sample is introduced at atmospheric pressure into a stainless steel loop. In the inject mode, the sample loop is rotated into the flowing stream of the mobile phase, and the sample is swept into the chromatographic column. These injectors are precise, function at high pressures, and can be programmed for use in automated systems.

Digitally controlled autosamplers that incorporate a loop injector are available commercially. These sophisticated devices are extremely precise and can be programmed for continuous and automated operation. In addition, the sample loop is flushed automatically with the mobile phase between samples to prevent sample carry over. The ability to inject multiple aliquots from a single sample vial or to add reagents from designated vials to derivatize the analyte just before injection are additional features of many autosamplers.

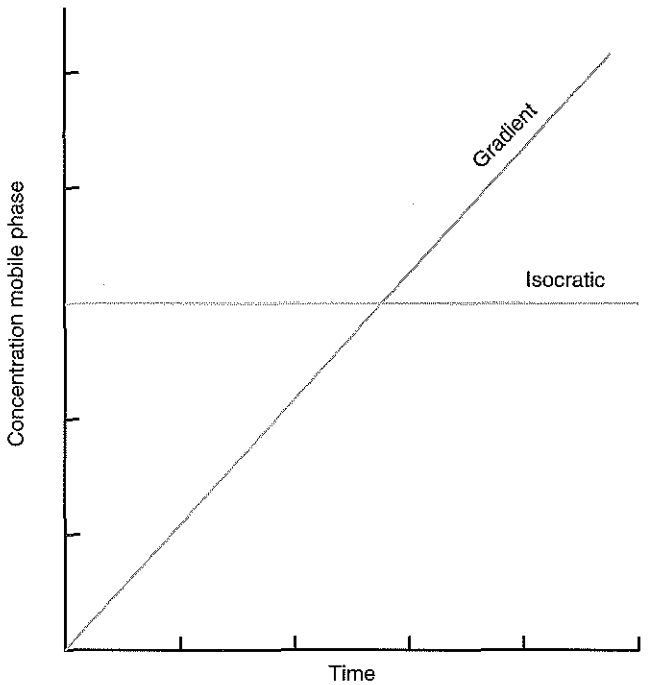

Figure 6-16 Examples of isocratic and gradient elution in LC. *LC*, Liquid chromatography.

Detectors

Many detectors have been developed for use with liquid chromatographs (Table 6-4). Examples include photometric, spectrophotometric, fluorometric, and electrochemical detectors. A key and integral component of such detectors is the flow cell (Figure 6-18), through which passes the eluate from the chromatographic column. Dissolved analytes are then detected and an electronic signal generated. (Mass spectrometers, which also have been used as LC detectors, are discussed in Chapter 7.)

Photometers and Spectrophotometers. UV and visible photometers measure the radiant energy absorbed by compounds as they elute from the chromatographic column (see Chapter 3). These detectors operate in the radiant energy regions of 190 to 400 nm and 400 to 700 nm, respectively. The devices are versatile and detect many solutes because most organic compounds absorb in the UV region, with a few in the visible region of the electromagnetic spectrum.

Photometers operate as either fixed-wavelength or variable-wavelength detectors. Most fixed-wavelength UV

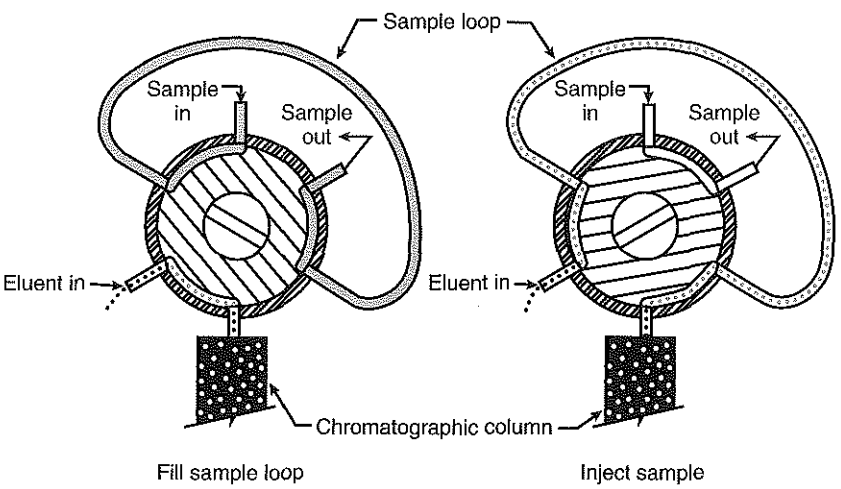

Figure 6-17 Cross-sectional view of a commonly used sample loop injector.

photometers use the intense 254-nm resonance line produced by a mercury arc lamp. This type of detector is extremely sensitive and operates at 0.005 absorbance units full scale (AUFS). To provide the fixed-wavelength detectors with greater flexibility, other less intense resonance lines of the mercury lamp are used. Alternatively a phosphor is placed between the lamp and the flow cell, and the emitted fluorescence resulting from the 254-nm excitation is used as the light source. This latter approach is used in the dual-wavelength photometers that operate at two fixed wavelengths (e.g., 254 nm and 280 nm). The intense 214-nm or 229-nm resonance lines of a zinc or cadmium arc lamp, respectively, also are used for detection at lower wavelengths, where more compounds absorb.

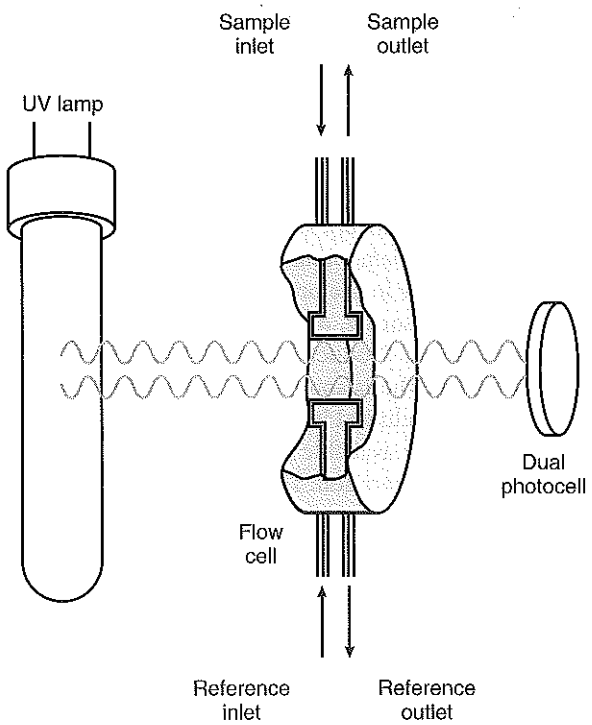

Figure 6-18 Optical schematic of a simple photometer and flow cell. *UV,* Ultraviolet.

The second type of photometer is the variable-wavelength detector. It operates at a wavelength selected from a given wavelength range. Thus the detector is "tuned" to operate at the absorbance maximum for a given analyte or set of analytes, which enhances greatly the applicability and selectivity of the detector (see Fig. 6-2). Another advantage of this detector is its ability to operate at lower wavelengths (e.g., 190 nm). Because more compounds (e.g., cholesterol) absorb at lower wavelengths, this capability enhances the versatility of the detector. At lower wavelengths, however, many solvents absorb UV light and cannot be used as mobile phases. Fortunately, acetonitrile and methanol, two widely used solvents in reversed-phase chromatography, have minimum UV absorptions at 200 nm.

In addition, diode arrays are used as HPLC detectors because they rapidly yield spectral data over the entire wavelength range of 190 to 600 nm in about 10 milliseconds. During operation the diode array detector passes polychromatic light through the detector flow cell. The transmitted light is dispersed by a diffraction grating and then directed to a photodiode array, where the intensity of light at multiple wavelengths in the spectrum is measured. Such detectors have been helpful in the identification of drugs in urine and serum.

Fluorometers. As discussed in Chapter 3, fluorescence occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength. Online fluorometers

TABLE 6-4 Examples of Detectors Used in High-Performance Liquid Chromatographs

Type of Detector	Principle of Operation	Range of Application	Detection Limit	Comments
UV photometer (fixed wavelength)	Measures absorbance of UV light	Selective	<1 ng	Analyte must absorb UV light or be derivatized
UV photometer (variable wavelength)	Measures absorbance of UV light	Selective	<1 ng	Detector can be "tuned" to a specific wavelength
Diode array	Measures absorbance of light	Selective	<1 ng	Detector provides complete spectra
Fluorometer	Measures fluorescence	Very selective	pg to ng	Analyte must fluoresce or be derivatized
Refractometer	Measures change in refractive index	Universal	1 µg	
Electrochemical	Electrochemically measures oxidized/reduced analyte	Selective	pg to ng	Detector is useful for catecholamines

UV, Ultraviolet.

are used in liquid chromatographs to detect fluorescing compounds as they elute from the column. In addition, either a precolumn or postcolumn reactor can be used to chemically tag a compound with a fluorescent label for subsequent detection. For example, amino acids or other primary amines often are labeled with either a dansyl or fluorescamine tag and followed by HPLC separation and fluorometric detection. Most fluorometers used with liquid chromatographs are relatively simple in design and extremely selective and sensitive for compounds fluorescing within the detector's operating wavelength range. Deuterium or xenon arc lamps or lasers have been used as light sources in such detectors.

Electrochemical Detectors. In amperometric electrochemical detectors (see Chapter 4), an electroactive analyte enters the flow cell, where it is either oxidized or reduced at an electrode surface under a constant potential. Electroactive compounds of clinical interest conveniently analyzed by HPLC with electrochemical detection include the urinary catecholamines (see Chapter 29). In addition, electrochemically active tags (e.g., bromine) are added to compounds such as unsaturated fatty acids or prostaglandins.

Coulometric detectors are also used. When placed in a series, such detectors are used to detect and quantify coeluting compounds that differ in their half-wave potentials (the potential at half-signal maximum) by at least 60 mV. These detectors are extremely selective and sensitive, with reasonably wide linear response ranges. They are used in the clinical laboratory for the analysis of metanephrines, vanillymandelic acid, homovanillic acid, and 5-hydroxyindole acetic acid in human urine without extensive sample preparation.

Computer

As with gas chromatographs, the incorporation of computer technology into HPLC instrumentation has resulted in cost-effective, easy-to-operate automated systems with improved analytical performances (see Figure 6-14). In these systems, a computer provides both system control and data processing functions. For details the reader should consult the previous discussion on the use of computers in gas chromatographs.

Practical Considerations

Several techniques affect the practical application of HPLC in the clinical laboratory, including those used to prepare samples and mobile phases.

Sample Preparation

Sample preparation is an important step in chromatographic analysis by HPLC and includes procedures for sample concentration, purification, and derivatization.

Sample Concentration and/or Purification. Concentrating or purifying an analyte in a sample is often necessary before separation and quantification by HPLC. Several liquid extraction and solid phase extraction (SPE) techniques are used for this purpose. The latter has become very popular because solid phase extraction cartridges or 96-well plate SPE formats greatly simplify sample preparation. The cartridges are usually 1- or 3-mL syringe barrels made of polypropylene that contain a stationary phase. The plate format uses smaller quantities of the stationary phase and requires smaller elution volumes. Both the cartridge and plate formats are available with disk designs that have small stationary phase–impregnated disks for use with small sample and elution volumes. Silica-based or polymeric normal-phase, reversed-phase, or ion-exchange (anion, cation, or mixed) stationary phases are available. Monolithic packings are also available. As an aliquot of urine or serum passes through the stationary phase, it retains the analytes. The column is then rinsed with solutions of different pH values or solvent compositions to selectively elute interfering substances. The analytes are then eluted with a different mobile phase. Alternatively, analytes are eluted directly, with unwanted solutes being retained on the cartridge. This approach is popular in the preparation of samples for therapeutic drug monitoring, drugs of abuse testing, and catecholamine analysis. Product manufacturers usually have a compilation of methods and protocols for specific analytes, including those of clinical interest.

Devices are now available for automated online extraction and sample preparation. These consist mainly of robotic arms and mechanisms for highly accurate and precise delivery of solvent volumes. Depending on the instrument, samples may be prepared and analyzed individually or in batches.

Sample Derivatization. For HPLC analyses, many analytes are chemically derivatized before or after chromatographic separation to increase their ability to be detected. For example, in automated amino acid analyzers, eluted amino acids are reacted with ninhydrin in a postcolumn reactor (see Chapter 20). The resulting chromogenic species are then detected with a photometer. Other examples include labeling amino acids or other primary amines with dansyl or fluorescamine tags either before or after the chromatographic step.

Preparation of Mobile Phase. In preparing the mobile phase, dissolved gases in the solvent must be removed or suppressed. The solvent must also be free of particulate matter. When the mobile phase is composed of two or more solvents, the solvents must be adequately mixed.

Solvent Degassing. A common problem in LC is the evolution of dissolved gas bubbles that evolve as the mobile phase passes from the high-pressure (column) side to the ambient-pressure (postcolumn) side of the chromatographic system. These bubbles must be removed or suppressed because they create an unstable electronic signal (noisy baseline) when they pass through a detector. Operationally, vacuum degassing, helium purging, postdetector back pressure, or vacuum membrane degassing are techniques used to prevent this problem.

With vacuum degassing, the mobile phase is stirred in a side-armed flask or mobile phase handling system under

reduced pressure. Nonpolar mobile phases require less than 1 minute to degas, but polar mobile phases require several minutes. Prolonged degassing under vacuum should be avoided, however, because it alters the mobile phase composition, especially when volatile solvents are used.

Another degassing technique, helium "sparging," requires a constant, gentle stream of helium bubbled through the solvents in the solvent reservoirs. The relatively insoluble helium extracts the dissolved gases, which then are vented into the atmosphere. Helium degassing is particularly useful with fluorescence detectors because it efficiently removes oxygen that quenches the fluorescence signal. Helium is expensive, however, and is best used with low-vapor-pressure solvents. Nonpolar solvents over time will be removed from the mobile phase mixture by the helium. Placing a drying agent in the helium line (between the helium tank and solvent reservoir) is helpful because it removes any water in the gas. Also, a back-pressure valve can be attached to the outlet of the system's detector, forcing gasses to remain in the solution until they have passed through the detector cell.

Vacuum membrane degassing uses PTFE tubing that is several meters long. As the tubing is permeable to gasses, solvents passing through the tubing are degassed when an external vacuum is applied. The efficiency of degassing is dependent on tubing length and solvent flow rate. Degassing can also be accomplished using Teflon AF tubing, which possesses excellent gas permeability characteristics. Thus degassing chamber internal volumes can be reduced to about 500 uL. In addition, gas-impermeable tubing can be used after the degassing to keep the solvent free of gasses. Vacuum membrane degassing systems can be purchased separately or as an integral part of an HPLC system. This economical form of degassing is satisfactory for most analytical procedures. Other degassing methods include mild heating and ultrasonic vibration of the mobile phase.

Solvent Clarity. Mobile phases should be prepared from HPLC-grade solvents free of particulate matter. Most commercial HPLC solvents are prefiltered. If they are not, however, they should be filtered through a 0.5-μm screen.

Solvent Mixing. During gradient operation, the HPLC solvents that comprise the mobile phase must be mixed adequately, most commonly with either a static or dynamic mixer. Static mixers rely on laminar-flow dynamics, whereas dynamic mixers use magnetic stirrers. Solvent viscosity affects mixing characteristics; inadequate mixing is detected by many UV detectors and may be expressed as an unstable baseline.

Safety

Normal laboratory precautions must be exercised during HPLC operation. The column effluent should be collected in a suitable container and stored appropriately before disposal. The explosive release of pressure in an HPLC system is not a major hazard; liquids compress only slightly and therefore accumulate little energy.

QUALITATIVE AND QUANTITATIVE ANALYSES

Chromatography is basically a separation technique. However it can be used for both qualitative [identifying the analyte(s) of interest] and quantitative analyses.

Analyte Identification

The retention time or volume at which an unknown solute elutes from a column or the distance traveled on a plate is often matched to that of a reference compound. The appearance of a solute peak, band, or spot at the same time as that of a reference compound is consistent with the two compounds being the same. The simultaneous appearance does not prove identity, however, because other compounds can have the same retention time as the reference compound.

In planar chromatography, reference compounds are chromatographed with the unknown sample. Tentative identification is made by comparison of the migration distances and detection characteristics of the reference compounds with those of the unknown analytes. If the R_f of the unknown analyte and the R_f of the reference compound do not match, the compounds are judged to be different. If they match, the compounds are presumed to be identical. However, as more than one compound can have the same R_f in a particular chromatographic system, the presumptive identification has to be confirmed by the use of specific spray reagents, antibody complexation, or isolation of the compound followed by chemical and/or instrumental analysis. Software is now available for compound identification by library searching of UV spectra based on corrected R_f values.[15]

With capillary GC and LC columns, it is possible to simultaneously introduce the components of a single injection into two columns made of dissimilar stationary phases. The columns are connected to separate detectors of the same or a different type. Matching the retention properties of a single analyte with a reference compound on two columns of dissimilar phases enhances the chance for correct identification of the analyte. The most reliable analyte identification, however, is provided by a detector that features structural information, such as a mass spectrometer (see Chapter 7).

Analyte Quantification

The electronic signals from the detector(s) are also used to produce quantitative information. Both external and internal calibrating techniques have been used. With external calibration, reference solutions containing known quantities of analytes are processed in a manner identical to the samples containing the analyte (Figure 6-19). A calibration curve of peak height, peak area, or spot density versus calibrator concentration is constructed and used to calculate the concentration of the analyte in the samples. With internal calibration, also called *internal standardization,* reference solutions of known analyte concentrations are prepared, and a constant amount of a different compound, the internal standard, is added to each reference solution and each

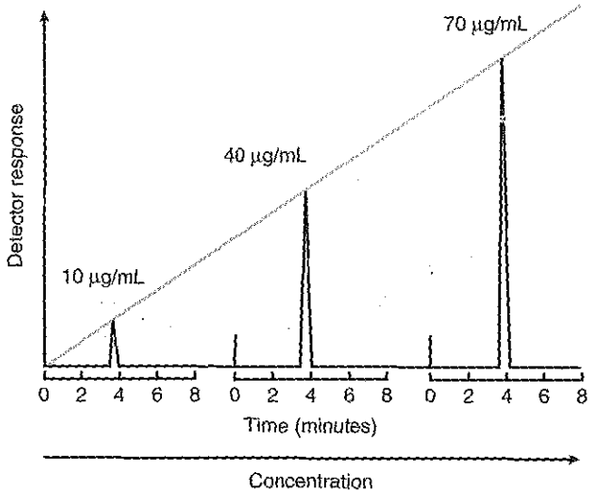

Figure 6-19 The use of external calibrators in the production of a calibration plot. *(From Krull I, Swartz M: Quantitation in method validation. LC-GC 1998; 16:1084-90.)*

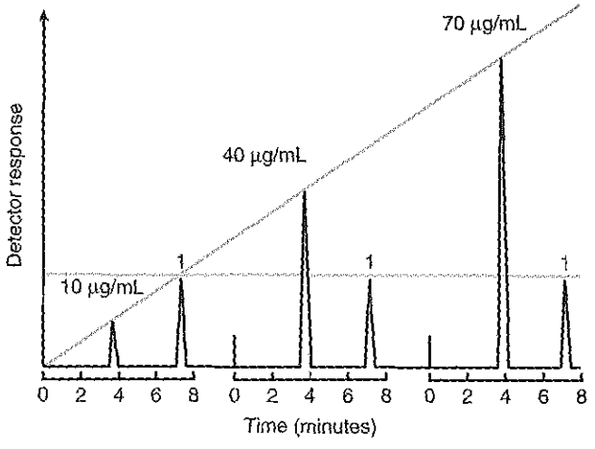

Figure 6-20 The use of internal calibrators in the production of a calibration plot (peak 1 being the internal standard). *(From Krull I, Swartz M: Quantitation in method validation. LC-GC 1998; 16:1084-90.)*

sample (Figure 6-20). By plotting the ratio of the peak height (or area) or spot density of the analyte to the peak height (or area) or spot density of the internal standard versus the concentration of the analyte, a calibration curve that corrects for systematic losses is constructed. This curve is then used to compute the analyte concentration in the samples by interpolation.

CHAPTER 7

Mass Spectrometry*

Thomas Annesley, Ph.D., Alan L. Rockwood, Ph.D., and Nicholas E. Sherman, Ph.D.

Mass spectrometry (MS) is a powerful qualitative and quantitative analytical technique that is used to measure a wide range of clinically relevant analytes. When MS is coupled with either gas or liquid chromatographs, the resultant analyzers have expanded analytical capabilities with widespread clinical applications. In addition, because of its ability to identify and quantify proteins, MS is a key analytical tool that is used in the emerging field of proteomics.

We begin this chapter with a discussion of the basic concepts and definitions of MS followed by discussions of MS instrumentation and clinical applications.

BASIC CONCEPTS AND DEFINITIONS

MS is the branch of science dealing with all aspects of mass spectrometers and the results obtained with them. A *mass spectrometer* is an analytical instrument that first ionizes a target molecule and then separates and measures the mass of a molecule or its fragments. *Mass analysis* is the process by which a mixture of ionic species is identified according to the mass-to-charge *(m/z)* ratios (ions).[88] The analysis is qualitative, quantitative, and extremely useful for determining the elemental composition and structure of both inorganic and organic compounds.

All MS techniques require an ionization step in which an ion is produced from a neutral atom or molecule. In fact development of versatile ionization techniques has led to MS being the excellent analytical tool it is today. In 2002 the Nobel prize was shared by John Fenn and Koichi Tanaka for their development of electrospray[28,29] and laser desorption[49,69,85] ionization, respectively.

Chemical, electron field desorption, laser desorption, photon, plasma desorption, spark, and *thermal* ionization are all used as primary ionization processes. *Secondary ionization* is the term used to describe a process in which ions are ejected from a surface as a result of bombardment by a primary beam of atoms or ions.[88] If low energy or "soft" ionization techniques are used, the mass of the target molecule can be determined. Advances in soft ionization techniques have extended the use of MS to the direct measurement of peptide and protein mass.[3,70] Ionization at higher energy results in more extensive fragmentation of target molecules.

A *mass spectrum* is represented by the relative abundance of each ion plotted as a function of its mass-to-charge *(m/z)* ratio (Figure 7-1). Usually, each ion has a single charge ($z = 1$); thus the *m/z* ratio is equal to the mass. The unfragmented ion of the original molecule is called the *molecular ion.* The ion with the highest abundance in the mass spectrum is assigned a relative value of 100% and is called the *base peak.* By using the relative abundance of each ion fragment, instrument-dependent variability is minimized, and the mass spectrum can be compared to spectra obtained on other instruments. Since the fragmentation at specific bonds can be predicted from their chemical nature, the structure of an analyte can be reconstructed from its mass spectrum. Computer-based libraries of spectra are available to assist in identification of the analyte(s).

When interfaced to a liquid or a gas chromatograph, the mass spectrometer functions as a powerful detector, providing structural information in real time on individual analytes as they elute from a chromatography column. Depending on the operating characteristics of the mass spectrometer and the analyte peak width, several mass spectral scans can be acquired across the peak. The sum of all ions produced is displayed as a function of time to yield a *total ion chromatogram.* The mass spectrometer is considered to be a "universal detector" because all compounds have mass

*The authors gratefully acknowledge the original contributions by Larry D. Bowers on which portions of this chapter are based.

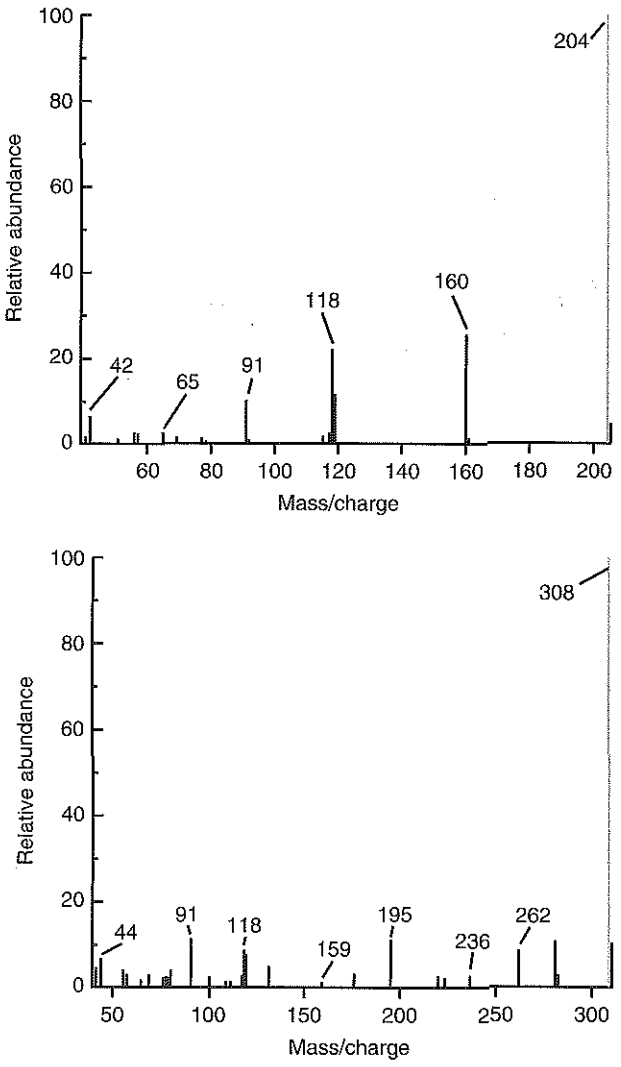

Figure 7-1 Mass spectrum of the pentafluoropropionyl **(A)** and carbethoxyhexafluorobutyryl **(B)** derivatives of d-methamphetamine.

and can, in theory, be detected. The data system can also be programmed to display only preselected ions acquired during the mass spectral scan. The resultant display is called an *extracted ion profile.* Both of these displays have the appearance of a chromatogram with signal intensity plotted as a function of time. Retention times can be measured and peak heights or peak areas can be integrated for use in quantitative analysis.

When only a few analytes are of interest for quantitative analysis and their mass spectrum is known, the mass spectrometer can be programmed to monitor only those ions of interest. This selective detection technique is known as *selected ion monitoring* (SIM). Because SIM focuses on a limited number of ions, more signal can be collected for each selected mass. This increases the signal-to-noise ratio of the analyte and improves the lower limit of detection. In general, however, an unknown is considered identified if the relative abundances of three or four ions agree within ±20% of those from a reference compound.

A distinct advantage of the mass spectrometer is that it can simultaneously differentiate and quantify a compound with a normal abundance of isotope from an analog enriched with a stable isotope (e.g., ^{2}H relative to ^{1}H, ^{13}C relative to ^{12}C, ^{15}N relative to ^{14}N, or ^{18}O relative to ^{16}O). A compound labeled with a stable isotope is used as an internal standard because it behaves nearly identically to the native compound during sample preparation and chromatographic analysis. The internal standard must have a sufficient amount of heavy isotope so that no naturally occurring ^{2}H or ^{13}C contributes significantly to the ion current. For the methamphetamine derivatives shown in Figure 7-2, an internal standard with at least three ^{2}H or ^{13}C atoms is preferred, because at this point the natural abundance of these isotopes is ~0.1% at 3 mass units above the molecular ion $[(M + 3)^{+}]$. The placement of the stable isotope atoms in the structure is also important. For example, the *m/z* 204 ion for metham-

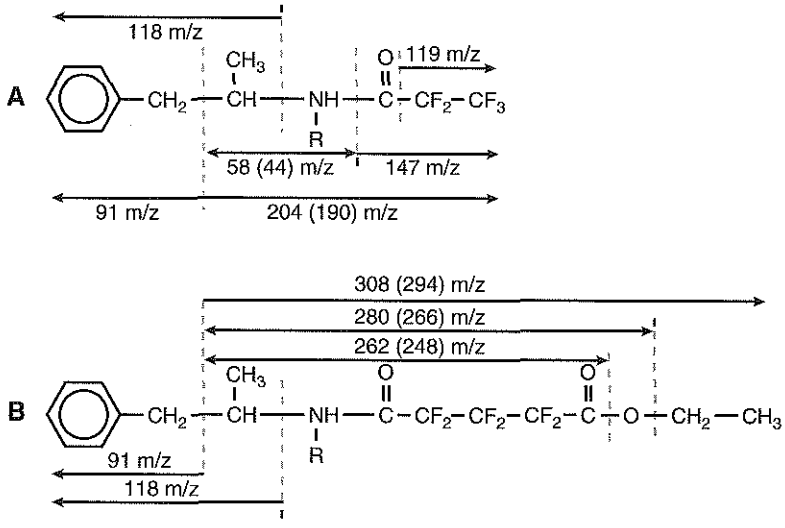

Figure 7-2 Fragmentation patterns for the pentafluoropropionyl **(A)** and carbethoxy-hexafluorobutyryl **(B)** derivatives of methamphetamine (R = CH_3) and amphetamine (R = H; masses in parentheses). Compare the predicted masses with the spectrum shown in Figure 7-1. Note that for the pentafluoropropionyl derivative, only one ion (204, 190 *m/z*) is characteristic of the aliphatic portion of the molecule.

phetamine represents the aliphatic portion of the molecule (loss of the aromatic ring). If five deuterium atoms were present on the aromatic ring of methamphetamine, the pentafluoropropionyl derivatives of both native and isotope-labeled drug would yield the *m/z* 204 ion. Similarly the stable isotope must be located so that it will not exchange with solvent molecules. In general, monitoring ions with higher mass results in lower limits of detection because there are fewer background ions. The ability to quantify a compound relative to an isotopic species of known or fixed concentration is known as *isotope dilution analysis,* and the specific mass spectrometric technique is known as *isotope dilution mass spectrometry* (IDMS). The IDMS technique has been used to develop definitive methods for a number of clinically relevant analytes.

INSTRUMENTATION

A mass spectrometer consists of an ion source, vacuum system, mass analyzer, detector, and computer (Figure 7-3).

Ion Source

Many approaches have been used to form ions, both in high-vacuum and near-atmospheric pressure conditions. *Electron ionization* (EI) and *chemical ionization* (CI) are ionization techniques used when gas phase molecules can be introduced directly into the analyzer from a gas chromatograph. In other analyses, such as high-performance liquid chromatography-mass spectrometry (HPLC-MS), electrospray ionization (ESI), sonic spray ionization (SSI), atmospheric pressure chemical ionization (APCI), and atmospheric pressure photoionization (APPI) interfaces are used as ionization sources.[14,26,33,39] Other ionization techniques include inductively coupled plasma (ICP), matrix-assisted laser desorption ionization (MALDI), atmospheric pressure matrix-assisted laser desorption (AP-MALDI), and fast atom bombardment (FAB).

Electron Ionization

In the EI gas phase molecules are bombarded by electrons emitted from a heated filament and attracted to a collector electrode (Figure 7-4). This process must occur in a vacuum to prevent filament oxidation. A potential difference of 70 eV generates electrons with sufficient energy that a near collision with most organic molecules produces a *radical* cation for EI that is both an ion and a radical.[88] This radical ion then undergos unimolecular rearrangement to produce a cation and a radical:

$$AB^{+\cdot} \rightarrow A^{+} + B^{\cdot}$$

As determined by their chemical stability, the relative proportions of molecular ion and fragment ions are reasonably reproducible. Positive ions are repelled or drawn out of the ionization chamber by an electrical field. The cations are then electrostatically focused and introduced into the mass analyzer.

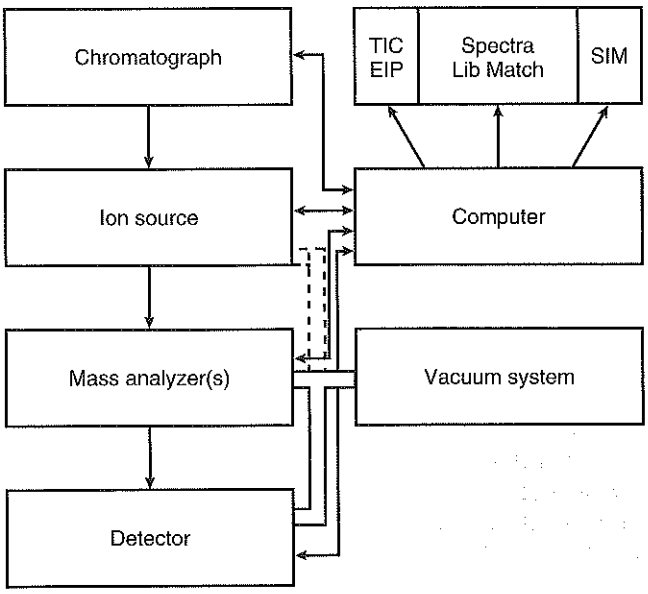

Figure 7-3 Block diagram of the components of a chromatograph-mass spectrometer system. The mass analyzer and detector are always under vacuum. The ion source may be under vacuum or under near-atmospheric pressure conditions, depending on the ionization mode. The computer system is an integral part of data acquisition and output.

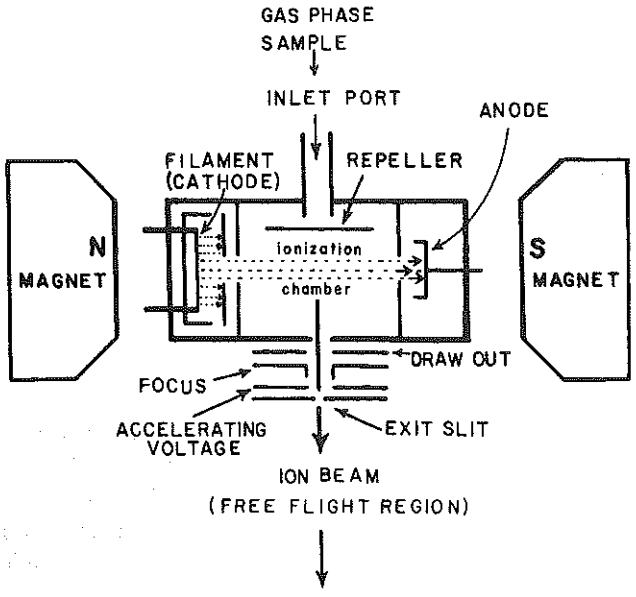

Figure 7-4 Electron impact ion source. The small magnets are used to collimate a dense electron beam, which is drawn from a heated filament placed at a negative potential. The electron beam is positioned in front of a repeller, which is at a slight positive potential compared with the ion source. The repeller sends any positively charged fragment ions toward the opening at the front of the ion source. The accelerating plates strongly attract the positively charged fragment ions.

Chemical Ionization

CI is a "soft" ionization technique in which a proton is transferred to, or abstracted from, a gas phase analyte by a reagent gas molecule. Typical reagent gases are methane, ammonia, isobutane, and water. The reagent gas is bled into a special CI source so the source pressure is increased to about 0.1 torr. An electron beam produces reactive species (such as CH_5^+ for methane). Collisions between the reactive reagent gas and the analyte cause proton and energy transfer. Because the protonated molecule is not highly excited in this process, relatively little fragmentation occurs. This is advantageous for analyte molecular mass determination and for quantification. Negative ion electron capture CI has become popular for quantification of drugs such as benzodiazepines. Negative ion formation occurs when thermalized electrons are captured by an electronegative substituent, such as chlorine or fluorine on the analyte. Thus the number of compounds undergoing negative ionization is small and background signal (noise) is decreased. When applicable, negative ion CI has very low limits of detection. Another use of CI is its application in the quadrupole ion trap (QIT) (discussed later). With a QIT, much lower gas pressures is used because the analyte and the reagent gas are stored for much longer periods of time than in a conventional CI source. This provides a wider range of potential CI reagents. For example, a vial of liquid acetonitrile can be attached to the ion trap and the gas vapor from the solvent used to produce reagent gas ions.

Electrospray Ionization

ESI is a technique in which a sample is ionized at atmospheric pressure before introduction into the mass analyzer.[92,94] The sample, typically an HPLC effluent, is passed through a narrow metal or fused silica capillary to which a 3 to 5 kV charge has been applied (Figure 7-5, *A*). The partial charge separation between the liquid and the capillary results in instability in the liquid that in turn results in the expulsion of a charged droplet series from a Taylor cone, which forms at the tip of the capillary. A coaxial nebulizing gas helps direct the charged droplets toward a counter electrode. The droplets evaporate as they migrate through the atmospheric pressure region, expelling smaller droplets as the charge-to-volume ratio exceeds the Raleigh instability limit. The proton- or ammonium-adduct of the molecule, which may be associated with solvent molecules, is "desolvated" to form "bare" ions, which then pass through a sampling cone and one or more extraction cones (skimmers) before entering the mass analyzer. ESI interfaces are available from all manufacturers of MS detectors, including (1) Agilent Technologies (http://www.agilent.com), (2) Applied Biosystems (http://www.appliedbiosystems.com), (3) Bruker Daltonics (http://www.daltonics.bruker.com), (4) Hitachi (http://www.hitachi.com/), (5) JEOL (http://www.jeol.com/), (6) LECO (http://www.leco.com), (7) Shimadzu (http://www.shimadzu.com), (8) Thermo Finnigan (http://www.thermo.com), (9) Varian (http://www.varianinc.com), and (10) Waters Micromass (http://www.waters.com). JEOL has also introduced a "cold electrospray" interface designed for the analysis of labile compounds.

One unique feature of ESI is the production of multiple charged ions, particularly from peptides and proteins. It is common to observe one charge for every 10 amino acid residues in a protein. For example, because a molecule of mass 20,000 can yield 20 charges, it can be detected at *m/z* 1000 (20,000/20) on a lower resolution and less expensive analyzer. This greatly extends the accessible mass range of such an instrument.

It should be noted that Figure 7-5, being a simplified illustration, shows the probe being directed toward the sampling cone of the mass detector. To enhance performance and minimize contamination of the mass detector, modern hardware configurations have offset the probe and/or the mass detector relative to the sampling cone. This results in the *z-spray* or *orthogonal* configuration employed by instrument manufacturers.

Sonic Spray Ionization

In ESI a high voltage is applied to the capillary. This yields charged droplets that are sprayed from the tip and evaporate to produce ions that enter the MS detector. The size properties of the droplets vary with flow rate, solvent composition, and chemical properties of the compounds being analyzed. An alternate ionization process has been introduced in which coaxial nitrogen gas, traveling at the speed of sound (Mach 1), is used to both create the spray and cause ions to be produced. This technique is known as sonic spray ionization (SSI). As the sonic velocity gas flows over the surface of the mobile phase exiting the capillary, two effects occur. First, droplet fission occurs as a result of shear stress created by the sonic gas flow, yielding fine charged droplets.[36] The charge density of the droplets is then enhanced by application of an external electric field.[35] Second, at sonic velocity, droplet size is at its minimum; this optimizes ionization efficiency. Since neither heating nor high voltage is required in SSI, this technique has been purported to be advantageous when highly polar solvents must be used, or when thermally unstable compounds are analyzed.

Atmospheric Pressure Chemical Ionization

APCI is similar to ESI. It takes place at atmospheric pressure, involves nebulization and desolvation, and uses the same sample and extraction cones as ESI. The major difference lies in the mode of ionization. In APCI no voltage is applied to the inlet capillary. Instead, a separate corona discharge needle,[12] located perpendicular to the capillary, is used to emit a cloud of electrons that ionize compounds after they are converted to the gas phase[37]:

$$CH_3OH + H^+ \rightarrow CH_3OH_2^+$$

$$A\,(\text{analyte}) + CH_3OH_2^+ \rightarrow AH^+ + CH_3OH$$

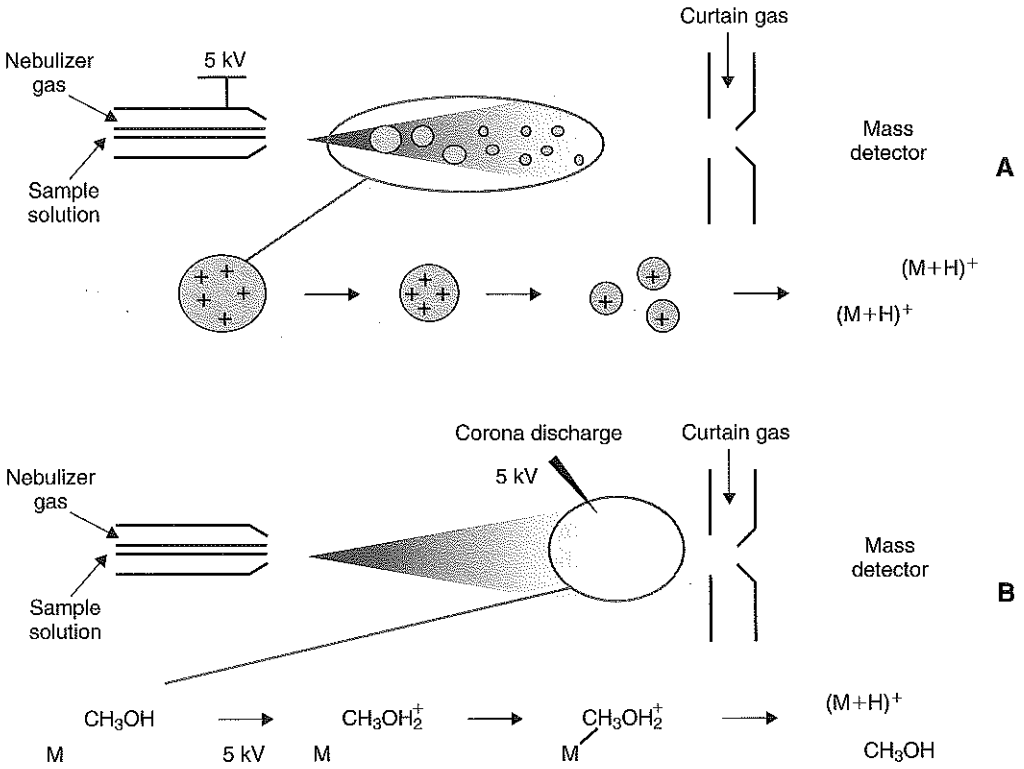

Figure 7-5 Schematics of **(A)** electrospray and **(B)** atmospheric pressure chemical ionization sources. Note the different points where ionization occurs, as described in the text.

or

$$H_2O + H^+ \rightarrow H_3O^+$$

$$A\,(\text{analyte}) + H_3O^+ \rightarrow AH^+ + H_2O$$

Because eluent molecules (e.g., water, methanol) are present in excess relative to the analytes in the sample, they are predominantly ionized and then act as a reagent gas that reacts secondarily to ionize analyte molecules (Figure 7-5, *B*). Because the products of these secondary reactions may contain clusters of solvent and analyte molecules, either a heated transfer tube or a countercurrent flow of a curtain gas, such as nitrogen, is used to decluster the ions. There is relatively little fragmentation, so much work with APCI has been for quantitative analysis or for tandem MS. As a well-proven interface, APCI sources are available from the major instrument manufacturers (see ESI section above).

Atmospheric Pressure Photoionization

Because of their ionization mechanisms ESI and APCI easily ionize polar compounds, but are less effective at ionizing many nonpolar compounds. APPI is a relatively new ionization technique that provides a complementary approach to ESI or APCI, and which is touted to be more universal across the polarity scale. First introduced by Syagen Technology (http://www.syagen.com), APPI sources are available through several manufacturers, including Agilent, Applied Biosystems, Bruker Daltonics, Thermo Finnigan, and Waters Micromass. The physical configuration of an APPI source is similar to that for APCI, but a photon flux is used instead of a corona discharge needle to generate ions in the gas phase.[74,83,84] The photon source is a krypton discharge lamp with a magnesium fluoride window for transmission of ultraviolet (UV) light, operated at a photon energy of 10 eV. This energy level has been carefully chosen because it is high enough to achieve the ionization potential thresholds for many classes of organic compounds, yet is low enough to be below the ionization thresholds for solvents, such as methanol, acetonitrile and water, and constituents of air. In theory this selective ionization should decrease charge-competition effects, allowing better quantitation and a potential higher dynamic range. The relatively lower ionization energy with APPI also minimizes fragmentation so that molecular ions predominate.[84] In APPI an ionizable dopant, such as toluene or acetone, is often infused coaxially to the nebulizer to provide a source of ions that provide charge or proton transfer to analytes, thus increasing the efficiency of analyte ionization.

Inductively Coupled Plasma

ICP is an atmospheric pressure ionization method. However, unlike most atmospheric pressure ionization methods, which are "soft" (i.e., producing little fragmentation), ICP is the ultimate in "hard" ionization, typically leading to complete atomization of the sample during ionization. Consequently, its primary use is for elemental analysis. In the

clinical lab, it is particularly useful for trace metal and heavy metal analysis in tissue or body fluids. ICP is extremely sensitive (e.g., parts per trillion) and is capable of extremely high dynamic ranges. The sample is typically prepared by acid digestion, and the liquid digest is introduced into the ion source via a nebulizer fed by a peristaltic pump. The nebulized sample is transmitted into hot plasma generated at atmospheric pressure by inductively coupling power into the plasma using a high-powered, radio frequency (RF) generator. A small orifice samples the plasma, and ions are transmitted to the mass analyzer through a series of differential pumping stages. The atmospheric sampling apparatus is similar to that of other atmospheric pressure ion sources, such as electrospray, except that the device must withstand the extremely high temperatures generated by the plasma. ICP-MS is comparatively free from most interference. However, some interferences can be extremely troublesome. Most interfering species are small polyatomics formed in the torch via ion-molecule reactions. For example ArO^+ interferes with iron at *m/z* 56. One solution to this problem is the dynamic reaction cell, which consists of a moderate pressure gas placed before the *m/z* analyzer. A reactant gas, such as NH_3, is bled into the reaction cell. The reactant gas reacts with polyatomic interferences and removes them before introduction into the *m/z* analyzer. The dynamic reaction cell is proprietary technology marketed by PE/Sciex (http://www.appliedbiosystems.com; http://www.sciex.com). The Agilent 7500c ICP-MS uses an octopole reaction system to remove the plasma and matrix-based interferences. Other suppliers of ICP-MS instruments include Thermo Finnigan, Thermo Elemental, and Varian.

Matrix-Assisted Laser Desorption/Ionization

MALDI was originally described in 1987.[43,44] The original work consisted of purely laser desorption/ionization where a sample was placed on a target and, in a combined process, desorbed and ionized so its mass could be measured. Limitations on size and stability of the analyte quickly led to the addition of a matrix to assist in this process. In the current method, the analyte is dissolved in a solution of matrix, a small molecular weight UV-absorbing compound, and this solution is placed on a target that can be introduced into the mass spectrometer. The matrix-to-analyte ratio is generally around 1000 to 1. As the volatile solvents evaporate, the matrix compound crystallizes and incorporates analyte molecules. Figure 7-6 illustrates the use of a UV laser to vaporize small amounts of matrix and analyte into a plume of ions that can be directed into a mass analyzer. MALDI has most classically been coupled with a time of flight (TOF) mass analyzer because it produces discrete, pulsed-ion packets, and because analysis by mass alone generally relies on the resolution and mass accuracy found in the TOF analyzer.

Atmospheric Pressure Matrix-Assisted Laser Desorption/Ionization

The MALDI source has been coupled to other mass analyzers, but these combinations have gained little popularity, generally because the MALDI source is under vacuum and most other sources are at atmosphere, and changing sources is not as straightforward as advertised. In 2000 an ion source was introduced[53] that produces ions in a manner similar to a traditional MALDI ion source but does so at atmospheric pressure (AP-MALDI).[66] The major advantage of this configuration is the ability to switch sources easily while coupling the inherent speed and multiple sample wells of traditional MALDI with mass analyzers capable of easily generating sequence information, such as ion trap or quadrupole TOF systems. The added ability to produce fragmentation overcomes a serious problem in eliminating ambiguous (or no) identifications obtained with protein mass fingerprinting (PMF). One current disadvantage is the poor fragmentation of the singly charged ions produced in the MALDI source, compared with the multiply charged ion produced in an electrospray source. The difference is not great for spectral confirmation but increases dramatically for de novo spectral interpretation. In collaboration with Mass Tech, Inc., AP-MALDI sources have been adapted to the Agilent LC/MSD, Bruker Esquire and Bio-TOF, Thermo Finnigan LCQ, and Waters Micromass Q-Tof instruments.

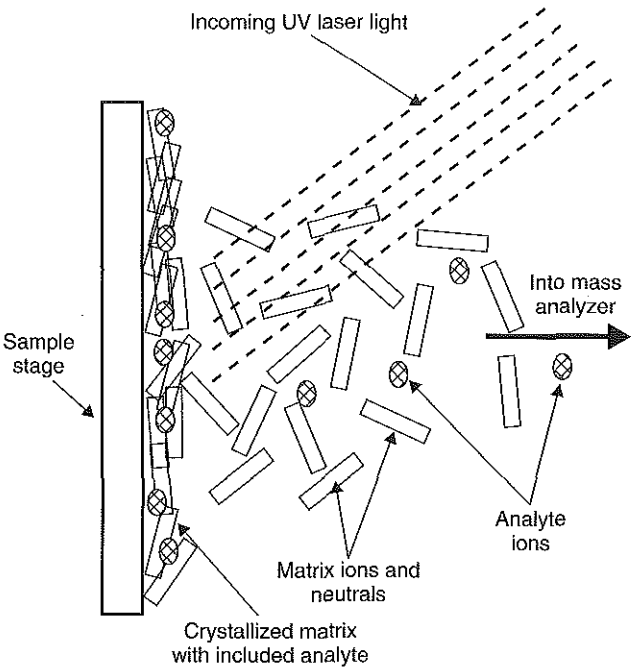

Figure 7-6 A generic view of the process of matrix-assisted laser desorption ionization. Co-crystallized matrix and analyte molecules are irradiated with a UV laser. The laser vaporizes the matrix, producing a plume of matrix ions, analyte ions, and neutrals. Gas-phase ions are directed into a mass analyzer.

Surface-Enhanced Laser Desorption/Ionization

A potential change in the area of MALDI involves the development of Surface-Enhanced Laser Desorption Ionization (SELDI).[40,41,64] This technique, developed by Ciphergen Biosystems (http://www.ciphergen.com/), combines affinity purification and MALDI on the target. The most common

setup involves producing a MALDI target surface modified with some type of affinity capture property (hydrophobic, ionic, immobilized metal affinity chromatography [IMAC], DNA, antibody, etc). The sample of interest, often in a complex mixture such as serum, is exposed to one or more of these affinity surfaces, and certain analytes will preferentially bind. The surface is washed to remove as much nonspecific binding as possible, and a matrix is added to enhance desorption and/or ionization. The target can then be analyzed by TOF or another method of choice. The interaction can be very specific, such as an antibody, and purify essentially one protein, or it can be specific for a class of compounds, for example, phosphorylated or glycosylated species. The major advantage is low sample loss as purification and analysis occur on the same surface.

Fast Atom Bombardment

Several techniques to produce ions from high molecular weight polymers have been developed. FAB produces ions when a high-velocity beam of atoms impacts the surface of a liquid containing the analyte(s). Protonization is thought to occur when analytes on the surface of vaporized droplets are transferred to the gas state. Since the bombardment occurs in high vacuum, the liquid used (e.g., glycerol) must have a high boiling point. FAB is used to ionize proteins and smaller molecules. Continuous flow FAB[10,11] allows automated sequential introduction of samples. It is often used in conjunction with tandem MS for the diagnosis of short-chain fatty acid acylcarnitine deficiencies from newborn blood spots.

Vacuum System

Ion separation in any of the mass analyzers requires that the ions do not collide with any other molecules during their interaction with the magnetic or electric fields. This requires the use of a vacuum from 10^{-3} to 10^{-9} torr, depending on mass analyzer type. The length of the ion path in the analyzer must be less than the mean free path length, unless collisions play a role in mass analysis. Fourier transform ion cyclotron resonance (FT-ICR), which will be discussed later, requires the lowest pressure (10^{-9} torr), and the QIT tolerates the highest pressure (10^{-3} torr). The mass analyzer is usually maintained at an elevated temperature (150 °C to 250 °C) to prevent gas molecules or organic compounds from adsorbing to the inner surfaces of the vacuum chamber. Routine quality assurance checks for vacuum leaks should include an evaluation of air and water in the mass analyzer.

Efficient high-vacuum pumps generally do not operate well near atmospheric pressure. Thus the vacuum system must have a mechanical vacuum pump to evacuate the system to a pressure where the high-vacuum pumps are effective. Mechanical pumps require routine maintenance, such as ballasting and replacing the pump oil. The diffusion pump is the least expensive and most reliable high-vacuum pump. Turbomolecular pumps and cryopumps are also used on mass analyzers. The high-vacuum pumps also require routine maintenance for optimal operation. A key consideration in construction of the vacuum system is pumping speed. The ability of the pump to maintain the vacuum by removing any gas (or solvent vapor) that enters the system determines the flow rate of gas or liquid that is introduced into the mass spectrometer. In general, higher pump capacities are associated with lower detection limits because noise arising from the gas background is reduced.

Mass Analyzers, Ion Detectors, and Tandem Mass Spectrometers

As mentioned earlier, "mass spectrometry" is a somewhat of a misnomer because mass spectrometers do not measure molecular mass, but rather they measure mass-to-charge ratio (m/z). This fact is fundamental to the physical operating principles of mass spectrometers and consequently impacts all aspects of instrumentation design, operation, and interpretation of results. The conventional definition of m/z creates a problem because it is defined as a dimensionless quantity,[73] which is not consistent with the equations of ion motion in the presence of electric and magnetic fields. These equations require units of mass divided by charge. Therefore in this section a slightly nonstandard definition of m/z will be used in which it has dimensions of mass divided by charge. Under this definition the numerical value of m/z is identical to the usual convention, provided that m is specified in daltons and z is specified in elementary charges. However, in actual calculations of ion motion it is best to convert these quantities to meter/kilogram/second (MKS) units to prevent mixing macroscopic and microscopic units.

The unit of m/z is sometimes referred to as the *Thomson* (Th) in honor of one of the pioneers of MS.[18,23] This notation distinguishes the quantity actually measured by mass spectrometers (m/z) from the quantity somewhat loosely (and incorrectly) associated with MS (mass), which is usually expressed as daltons, Da, or equivalently as unified atomic mass units, u.

General Classes of Mass Spectrometers

Mass spectrometers are broadly classified into two groups, beam-type instruments and trapping-type instruments. In a beam-type instrument, the ions make one pass through the instrument and then strike the detector, where they are destructively detected. The entire process, from the time an ion enters the analyzer until the time it is detected, generally takes microseconds to milliseconds. In a trapping-type analyzer ions are held in a spatially confined region of space by a combination of magnetic, and/or electrostatic, and/or RF electrical fields. The trapping fields are manipulated in ways that allow m/z measurements to be performed. Trapping times may range from a fraction of a second to minutes, though most clinical applications are at the low end of this range. Detection of the ions in a trapping-type instrument may be destructive or nondestructive, depending on the specific type of mass spectrometer used. Additional discussions of mass analyzers, tandem mass spectrometers, and ion detectors are available.[24,80]

Beam-Type Designs

The three main beam-type mass spectrometer designs are quadrupole, magnetic sector, and TOF. It is convenient to categorize beam-type instruments into two broad categories, those that produce a mass spectrum by scanning the *m/z* range over a period of time (quadrupole and magnetic sector) and those that acquire successive instantaneous snapshots of the mass spectrum (TOF). This categorization is not hard and fast. Certain instrument designs can be adapted to either scanning or nonscanning operation. Nevertheless, the categorization is a useful one because it covers the majority of instruments currently available, and because scanning and nonscanning instruments are adapted to different optimal usages.

Quadrupole. Quadrupole mass spectrometers, sometimes known as quadrupole mass filters (QMF), are currently the most widely used mass spectrometers, having displaced magnetic sector mass spectrometers as the standard instrument. Although these instruments lag behind magnetic sector instruments in terms of sensitivity, upper mass range, resolution, and mass accuracy, they offer an attractive and practical mix of features that accounts for their popularity, including ease of use, flexibility, adequate performance for most applications, relatively low cost, noncritical site requirements, and highly developed software systems.

A quadrupole mass spectrometer consists of four parallel electrically conductive rods arranged in a square array (Figure 7-7). The four rods form a long channel through which the ion beam passes. The beam enters near the axis at one end of the array, passes through the array in a direction generally parallel to the axis, and exits the far end of the array. The ion beam entering the quadrupole array may contain a mixture of ions of various *m/z* values, but only ions of a very narrow *m/z* range (typically $\Delta m/z \approx 1$) are successfully transported through the device to reach the detector. Ions outside this narrow range are ejected radially. The $\Delta m/z$ range represents a passband, analogous to the passband of an interference filter in optics (see Chapter 3), which is why quadrupole mass spectrometers are often referred to as "mass filters" rather than "mass spectrometers."

Quadrupole mass spectrometers rely on a superposition of RF and direct current (DC) potentials applied to the quadrupole rods. Considering first the DC component, DC voltages are applied to the electrodes in a quadrupolar pattern. For example, a positive DC potential is applied to electrodes 1 and 3, as indicated in Figure 7-8, and an equivalent negative DC potential is applied to electrodes 2 and 4. The DC potentials are relatively small, of the order of a few volts. Superimposed on the DC potentials are RF potentials, also applied in a quadrupolar fashion. The RF potentials range up to the kilovolt range, and the frequency is of the order of 1 MHz. The frequency is typically fixed, which will be considered the case throughout this discussion, though variable frequency operation is possible.

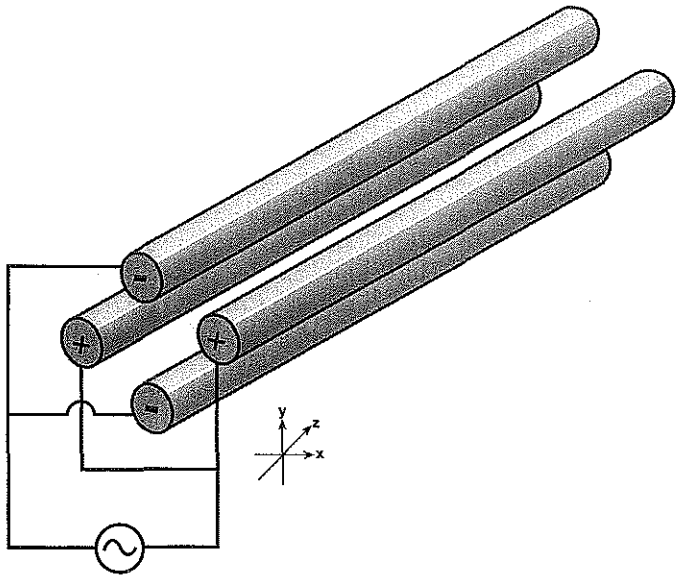

Figure 7-7 Diagram of quadrupole mass filter, including the RF part of the voltages applied to the quadrupole rods.

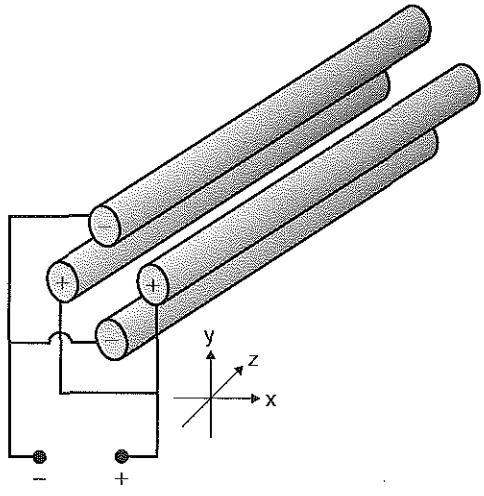

Figure 7-8 DC voltages applied to quadrupole rod assembly.

The device may be operated in either a SIM mode or a scanning mode. In SIM mode, both the DC and RF voltages are fixed. Consequently, both the center of the passband and the width of the passband are fixed. For example, the mass spectrometer may be set to pass ions of *m/z* 363 ± 0.5. Both the center *m/z* and the $\Delta m/z$ can be adjusted by the appropriate choice of DC and RF.

In the scanning mode of operation, the RF and/or DC voltages are continuously varied to scan a range of *m/z* values. As with SIM mode, the $\Delta m/z$ is also determined by the RF and DC voltages. Usually the scan function is designed to maintain a constant $\Delta m/z$ across the full *m/z* range. Thus the resolution increases as *m/z* increases. The value of $\Delta m/z$ is frequently chosen in the range 0.5 to 0.7 to resolve isotopic peaks across the full *m/z* range.

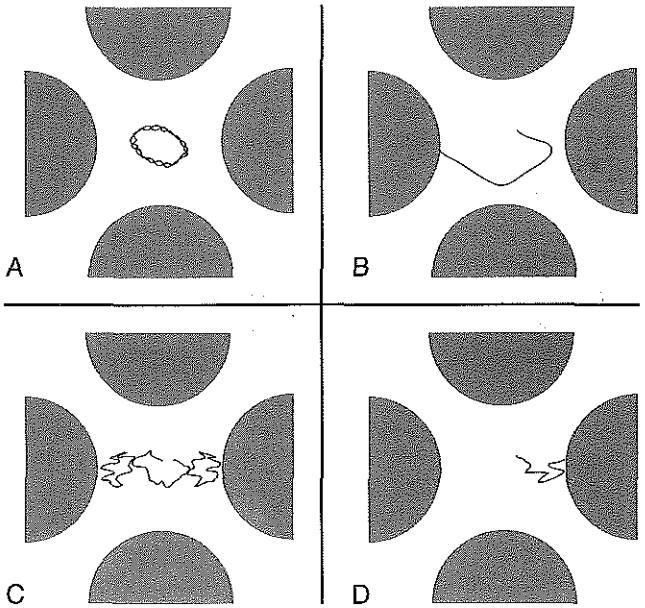

Figure 7-9 Ion trajectories showing confinement and ejection in quadrupole mass filters. **A,** Ion confinement by RF-only field. **B,** Ion ejection by RF-only field. **C,** Ion confinement with a combination of RF and DC fields. **D,** Ion ejection with a combination of RF and DC fields. All trajectories were simulated using Simion.[20]

The physical principles underlying the operation of a quadrupole mass spectrometer require the solving of a complicated differential equation, the Mathieu equation.[22] In operation when an ion is subjected to a quadrupolar RF field, its trajectory can be described qualitatively as a combination of fast and slow oscillatory motions. For descriptive purposes, the fast component will be ignored here and the slow component emphasized, which oscillates about the quadrupolar axis and resembles the motion of a particle in a fictitious harmonic "pseudopotential." The frequency of this oscillation is sometimes called the *secular frequency.*

The "effective force" associated with the pseudopotential points inward toward the quadrupolar axis and is proportional to the distance from the axis. It therefore acts as a confining force, preventing ions from being ejected radially from the quadrupolar assembly. Figure 7-9, *A* shows an example of an ion confined by an RF-only quadrupole. Below a certain *m/z* cutoff frequency (which depends on the frequency and amplitude of the RF field) ions are ejected rather than confined. Figure 7-9, *B* shows an example of an ion ejected by an RF-only quadrupolar field. This establishes the low mass cutoff for the *m/z* pass band. The effective confining force is strongest just above the low *m/z* cutoff, and then decreases asymptotically toward zero at high *m/z*.

The DC part of the quadrupolar potential is independent of *m/z*. Positive ions are attracted toward the negative poles. Negative ions are attracted toward the positive poles. Attraction increases as the distance from the quadrupolar axis increases. Since a quadrupolar DC potential always has both negative and positive poles, the quadrupolar DC potential always contributes to ejection in at least one direction. Whether ejection of an ion of a particular *m/z* actually occurs depends on whether the ejecting force caused by the quadrupolar DC potential overcomes the effective confining force caused by the RF potential. Above a certain *m/z* value the DC part dominates, and ions are ejected radially from the device. This establishes an upper *m/z* limit for ion transmission. Figures 7-9, *C* and *D* show examples of ion trajectories under the influence of combined RF-DC fields, one being confined and the other being ejected. Trajectories in Figure 7-9 were calculated using the Simion ion optics computer program.[20]

A rigorous description of low- and high-mass cutoffs is found in so-called stability diagrams, which graphically describe the lower and upper *m/z* cutoffs of a quadrupole mass spectrometer in terms of parameters related to voltages, frequencies, and *m/z*. An earlier edition of this book presents an example of a stability diagram. However, to fully understand the meaning of the stability diagram, one must delve more deeply into a mathematical description than can be accommodated here.

A large number of manufacturers make numerous quadrupole mass spectrometer models. A few prominent companies among the many in the field include Agilent, Thermo Finnigan, Waters Micromass, and Applied Biosystems/MDS Sciex. Most QMFs are intended primarily for use with separations, such as GC or LC. Nearly any ion source imaginable is marketed with one quadrupole mass spectrometer or another, including EI, ESI, APCI, ICP, and others.

The combination of lower and upper *m/z* limits establishes a passband ($\Delta m/z$), and ultimately a resolution [$(m/z)/(\Delta m/z)$]. Generally quadrupole instruments are limited to a resolution of several thousand, which is sufficient to achieve isotopic resolution for singly charged ions of *m/z* as high as several thousand. However, technical advances have enabled quadrupole mass spectrometers to achieve resolutions exceeding 10,000. The Thermo Finnigan TSQ Quantum Ultra AM is an example of such an instrument. The benefits of high resolution include reduction of interferences. In addition, high resolution, combined with high accuracy electronics, has enabled the measurement of exact masses using quadrupole instruments. Exact mass measurements are useful for confirmation of a chemical formula.

Magnetic Sectors. Because magnetic sector mass spectrometers are rarely used in the clinical laboratory and are rapidly losing popularity among mass spectrometrists generally, they will not be described in detail here. For a good introduction to magnetic sector technology, refer to the previous edition of this book. It should be noted, however, that these classic mass spectrometers are easy to understand (given a basic understanding of physics), are versatile, reliable, highly sensitive, and in their "double focusing" variation are capable of very high *m/z* resolution and mass

accuracy. However, they are typically expensive, large, and heavy. In addition, they have the reputation of being difficult to use. Consequently, other instruments have largely displaced magnetic sector mass spectrometers. However, there are two small bench top double focusing magnetic sector mass spectrometers that are potentially interesting to clinical chemists, the LCmate and the GCmate, both from JEOL.

Time of Flight. TOF mass spectrometry (TOF-MS) is a nonscanning technique where a full mass spectrum is acquired as a snapshot rather than sweeping through a sequential series of *m/z* values while sampling the sample. In recent years, TOF mass spectrometers have become very popular. They have a number of advantages, including a nearly unlimited *m/z* range, high acquisition speed, high mass accuracy, moderately high resolution, high sensitivity, and reasonable cost. They are also well adapted to pulsed ionization sources, which is an advantage in some applications, particularly with MALDI and related techniques.

A significant advantage of modern TOF mass spectrometers is that some of them produce exact mass measurements, typically with low parts per million (ppm) accuracy. This allows TOF measurements to confirm the molecular formula of a compound. Unlike magnetic sector instruments, which are also capable of exact mass measurements, exact mass measurements by TOF are practical in routine chromatography experiments and are therefore potentially useful to the clinical chemist.

TOF mass spectrometers are conceptually simple to understand as they are based on the fact that a lighter ion travels faster than a heavier ion, provided that both have the same kinetic energy. Figure 7-10 presents a simplified conceptual diagram of a TOF mass spectrometer. It resembles a long pipe. Ions are created or injected at the source end of the device and are then accelerated by a potential of several kilovolts. They travel down the flight tube and strike the detector at the far end of the flight tube. The time it takes to traverse the tube is known as the flight time, which is related to the mass-to-charge ratio of the ion.

The flight time for an ion of mass m and kinetic energy E to travel a distance L in a region free of electric fields is given by:

$$t = L\left(\frac{m}{2E}\right)^{1/2} \quad (1)$$

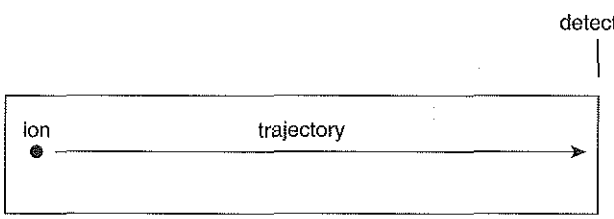

Figure 7-10 Diagram of simplified time of flight mass spectrometer.

A sample calculation for an ion of molecular weight 200 Da (3.32×10^{-25} kg) with a kinetic energy of 10 keV (1.60×10^{-15} J), traveling through a distance of 1 m, yields a flight time of 10.18 microseconds, and an ion of molecular weight 201 takes just 25 nanoseconds longer. To accurately capture such fleeting signals, the data recording system must operate on a ~1 nanosecond time scale. Recent advances in signal processing electronics have made this practical at relatively modest cost, and this has been a major factor in the rise in popularity of TOF-MS.

TOF is inherently a pulsed technique, and it couples readily to pulsed ionization methods, with MALDI being the most common example. A variety of MALDI-TOF mass spectrometers are offered by vendors. Examples include the Waters Micromass MALDI-LR, the Voyager-DE PRO Biospectrometry Workstation from Applied Biosystems (separate from Applied Biosystems/MDS Sciex), and the ultraflex from Bruker Daltonics. MALDI-TOF makes its biggest impact in the area of protein and peptide identification and is presently little used for quantitative analysis because the shot-to-shot variation of signal amplitude makes quantitation difficult.

Unlike many mass spectrometers, which allow the use of several different ionization methods on the same instrument, MALDI-TOF instruments are generally single purpose, being devoted exclusively to MALDI. In practice, EI and ESI methods are also used with TOF mass spectrometers. However, the continuous nature of these sources causes a natural mismatch to TOF-MS, which is a pulsed technique. The traditional way to couple a continuous ion source to a TOF-MS is to dynamically deflect the ion beam past a narrow slit, thus generating a pulsed ion beam at the exit side of the slit.[9] However, this results in low sensitivity as more than 99% of the ion beam is discarded.

To decrease this loss in sensitivity, the beam is injected orthogonal to the axis of the TOF-MS.[21,54,55,78,79] During the injection period the acceleration voltage is turned off. Once the injection region is filled with the traversing beam, the acceleration voltage is suddenly turned on, and the TOF timing cycle starts. The process is cycled repeatedly. The overall duty cycle for this method can be much more than 10%, a vast improvement over the traditional method. For full spectrum sensitivity with continuous ion sources, orthogonal injection TOF mass spectrometers are generally considered the most sensitive of all mass spectrometers. However, for the monitoring of a single *m/z* rather than a full mass spectrum, the use of SIM mode with a quadrupole MS provides superior sensitivity.

The conceptual simplicity of TOF-MS disappears when one considers actual instrumentation design. A good understanding of this issue is important in the selection and use of TOF mass spectrometers because there is a good deal of confusion about the true significance of terms like "linear," "reflectron," "orthogonal acceleration," "delayed extraction," and so forth. This may lead to poor selection and use of instruments.

Resolution is of primary concern. Assumptions underlying equation (1) are that ions all have the same kinetic energy, and that they are never subjected to electric fields. In practice neither assumption holds.

The kinetic energy, E, is imparted to the ion beam primarily via acceleration through an electric field. Each ion starts at a different point in the voltage gradient, and hence each ion acquires a different kinetic energy, resulting in a spread of velocities and flight times as inferred from equation (1). This ultimately leads to a loss of resolution. Early in the development of TOF-MS, Wiley and McLaren[93] showed that proper design of the acceleration field profile produces a compensating effect. In the Wiley-McLaren design, ions starting at the higher end of the potential gradient spend more time in the acceleration region than those starting at the lower end. This extra time compensates for the fact that the higher energy ions spend less time traveling through the field-free region. Wiley-McLaren instruments are classed as "linear" TOF mass spectrometers because ion motion is substantially unidirectional from source to detector.

Thermal motion provides another source of kinetic energy variation. Typical thermal energies are of the order of 0.025 eV, whereas a typical acceleration potential of a TOF mass spectrometer is 5000 V. The direct effect of a variation of 0.025 eV out of 5000 produces negligible effect on equation (1). Instead the resolution degradation is primarily a result of the so-called turnaround time, which occurs during the initial part of the flight time when ions are being accelerated up to full flight energy. Consider two ions with 0.025 eV of kinetic energy. In the acceleration region of the instrument one ion initially travels down the potential gradient (in the direction of the detector), and the other travels up the potential gradient. It takes notable time to turn the trajectory of the second ion around so it is traveling down the potential gradient, and this results in a notable loss of resolution for the instrument, limiting simple TOF mass spectrometers to a resolution of a few hundred.

There are two main approaches to solving the turnaround time problem. One is to extend the flight time of the ions so that the turnaround time is a smaller percentage of the total time, and the second is to inject ions into the instrument in a direction orthogonal to the flight tube of the TOF mass spectrometer. The first approach, extending the flight time, cannot be done by simply lengthening the field-free region. To do so would upset the fine balance inherent in the Wiley-McLaren design. Scaling up the dimension of the complete instrument without a change of basic configuration is also ineffective because the turnaround time increases with the scale of the instrument. What is required is to lengthen the flight path without introducing additional dispersion to the flight time. This is done using a device known as a "reflectron."[60] A reflectron consists of a length of field-free region, followed by an ion reflector. The reflector consists of a potential gradient that acts as an ion mirror. High-energy ions penetrate farther into the mirror and spend greater time in the mirror than low-energy ions. This compensates for the fact that high-energy ions spend less time traversing the field-free region.

Interestingly, reflectrons and Wiley-McLaren designs are similar from the point of view of their ion optics designs. Both use the same electric field profiles but differ in the type of resolution-degrading effect for which they are corrected. Wiley-McLaren designs are corrected for changes in start positions of ions (related to initial ion potential energy), and reflectrons are corrected for changes in the kinetic energy of ions. If a reflectron is added to a Wiley-McLaren section, the total flight time is extended without increasing the turnaround time, and the resolution increases. This is particularly effective if the Wiley-McLaren section is short and the reflectron section is long, because this design approach minimizes turnaround time.

The second approach to solving the turnaround time problem is to inject ions into the instrument in a orthogonal direction to the flight tube of the instrument. This was already discussed in relation to the interfacing of continuous ion sources to TOF mass spectrometers, and it was shown that this method results in an increase in sensitivity. By a fortunate coincidence, the method also produces an increase in resolution. This method relies on the fact that ions injected in a direction nearly perpendicular to the flight tube have a very small velocity component in the direction of the flight tube. Hence, the turnaround time is negligible. This allows even a Wiley-McLaren design to achieve a resolution of several thousand. An example of this approach is the Jaguar mass spectrometer marketed by LECO, which routinely operates at a resolution of 2500. Jaguar is based on an improved Wiley-McLaren design somewhat whimsically referred to as an "inverted perfectron."[67,75] Thus even a linear TOF-MS can be capable of quite good resolution if it is properly designed, and for many applications a reflectron may not be necessary.

Most TOF mass spectrometers used today with continuous-ion sources combine all three resolution-enhancing techniques. They use orthogonal injection into a short Wiley-McLaren stage, followed by a reflectron stage. A well-designed instrument of this type is capable of resolution well in excess of 5000, and resolution exceeding 20,000 has been reported in some cases. The Waters Micromass LCT, the Waters Micromass GCT, the Bruker Daltonics BioTOF II, the Agilent LC/MSD TOF, and the JEOL AccuTOF are typical examples of modern high performance reflectron TOFs interfaced to continuous-ion sources.

The resolution-degrading effects of variable kinetic energy also appear in TOF mass spectrometers using pulsed ion sources, such as MALDI and SELDI. Ion production in MALDI involves ejection of ions from a solid matrix as a result of a laser pulse. Ions are ejected with a distribution of kinetic energies, and this degrades the resolution available in a simple linear MALDI instrument. One technique for increasing resolution is to delay the application of acceleration voltage after application of the ion-forming laser pulse.

This is sometimes referred to as delayed extraction. A second technique is to use a reflectron. More recently, orthogonal introduction of ions has been introduced, in analogy to the orthogonal introduction of ions discussed above. The prOTOF 2000 marketed by Perkin Elmer Sciex is an instrument using orthogonal introduction. The prOTOF 2000 also uses collisional cooling in the interface between ion source and mass analyzer.

The technical features of TOF-MS lead to several operational advantages. TOF-MS is extremely fast. The fundamental repetition rate of most TOF-MS instruments is 5000 spectra/s or greater. This is far too fast for most applications, but signal averaging electronics allow the TOF instrument to be cycled at full speed (greater than or equal to 5000 spectra/s), while storing spectra at a lower rate (1 to 500 spectra/s). The high speed of TOF-MS also allows it to be interfaced to high-speed separations. For example, a TOF-MS capable of storing 100 spectra/s could easily handle chromatographic peak widths of 0.1 second. The Jaguar is an example of a high-speed, LC-capable instrument (100 spectra/s), and the Pegasus, also marketed by LECO, is a high-speed, GC-capable instrument (500 spectra/s).

TOF-MS is not only fast, but it is also a nonscanning technique. Each mass spectrum is an instantaneous snap-shot of the sample composition. This simplifies the use of MS as a chromatographic detector, because it eliminates peak skew. Peak skew is a distortion of mass spectra from scanning instruments when sample composition is dynamically changing. For example, assume that the mass spectrum is being scanned from low to high, and that it is monitoring the elution of a chromatographic peak. On the leading edge of the peak, the intensities at the high-mass end of the mass spectrum will be exaggerated, and on the trailing edge of the chromatograph the intensities of the low-mass end of the mass spectrum are exaggerated. By contrast the spectrum from a TOF-MS is undistorted, regardless of what part of the chromatographic peak is being sampled.

The lack of peak skew and high acquisition speed also facilitate the ability to mathematically deconvolute overlapping chromatograms. This technique attempts to resolve compounds whose chromatographic bands are highly overlapped. It requires that the compounds to be resolved have spectra that are not identical, though spectra can be quite similar. It also requires that the compounds are not perfectly co-eluting, though their chromatograms can be highly overlapped.

Use of deconvolution is advantageous when (1) there are many samples across the chromatographic peak, (2) there is no skewing of the spectra across the chromatographic peak, (3) full mass spectra are used, and (4) the signal-to-noise ratio is high. Of all mass spectrometer technologies available today, TOF-MS best fulfils all these requirements. AMDIS is freely available software for performing this kind of deconvolution,[59] and several instrument vendors also offer proprietary software for performing deconvolution. For example, the Pegasus from LECO, the TEMPUS from Thermo Finnigan, and the GCT from Waters Micromass all have deconvolution software available for their data systems. These deconvolution strategies are especially successful with very high speed GC-MS methods and show great potential for clinical applications as throughput and turnaround time become ever more important.

Another area where TOF-MS has an advantage is in high-mass analysis where its mass range is nearly unlimited. In MALDI-TOF, for example, it is not unusual to detect proteins with molecular weights exceeding 100,000. The ability for high-mass analysis is expected to increase in importance as clinical laboratories embrace proteomic-based diagnostic methods.

Trapping-Mass Spectrometers

In contrast to beam-type designs, these mass spectrometers are based on the trapping of ions to capture and hold ions for an extended amount of time in a small region of space. Trapping times vary from a fraction of a second to minutes. Unlike beam-type instruments, the division between scanning and nonscanning instruments has less meaning for ion-trapping instruments. The main practical difference between scanning and nonscanning instruments relates to peak skew, as discussed in the section on TOF. In terms of producing skewed spectra, trapping devices are more similar to nonscanning instruments, such as TOF (no skew) than to scanning instruments. This is because the sample is captured in an instant and then analyzed at leisure. Because the sample is captured in an instant there is no skewing of the spectra, regardless of whether the *m/z* analysis is performed by a scanning procedure or a nonscanning procedure.

Traditionally, ion traps have been divided into three classes: QIT, which rely on RF fields to provide ion trapping; a linear ion trap, which is closely related to the QIT in its operating principles; and ion cyclotron resonance (ICR) mass spectrometers, which rely on a combination of magnetic fields and electrostatic fields for trapping.

Quadrupole Ion Trap. QITs are primarily used as GC or HPLC detectors. They are relatively compact, inexpensive, and versatile instruments, excellent for exploratory studies, structural characterization, and sample identification. They are also used for quantitative analysis, though quantitative analysis is not the best use for these devices.

The operation of the QIT is based on the same physical principle as the quadrupole mass spectrometer described above. Both devices make use of the ability of RF fields to confine ions. However, the RF field of an ion trap is designed to trap ions in three dimensions rather than to allow the ions to pass through as in a QMF, which confines ions in only two dimensions. This difference has a significant impact on the operation and limitations of the QIT. The physical arrangement of a QIT is different from that of a QMF. If an imaginary axis is drawn through the *y*-axis of the quadrupole rods, and the rods are rotated around the axis, a solid ring with a hyperbolic inner surface results from the *x*-axis pair of rods.

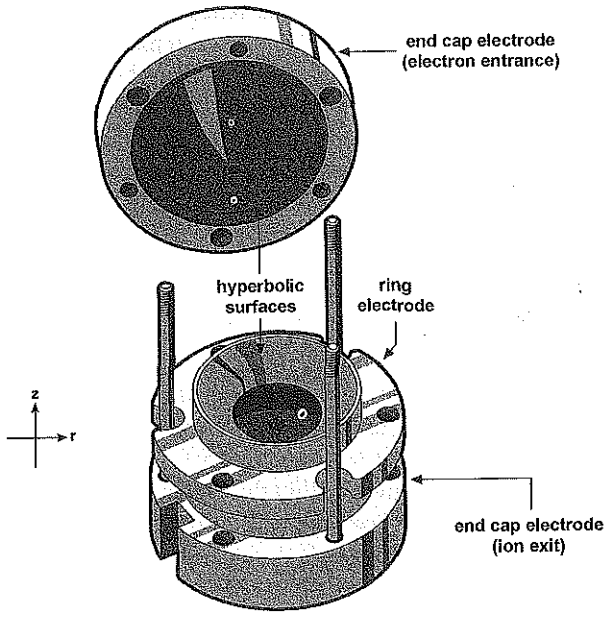

Figure 7-11 Diagram of quadrupole ion trap.

The two *y*-axis rods form two solid endcaps. The description of the fields within the electrodes must now include a radial component and an axial (between the endcaps) component. This slightly changes the precise conditions required for ion confinement when compared with a QMF, though the qualitative description of ion confinement discussed above is still valid.

A diagram of an ion trap mass spectrometer is given in Figure 7-11. The trap is quite small, of the order of a few centimeters in length. The trapping of ions, by itself, would be little more than an oddity of physics were it not for the fact that ions within the trap can be manipulated in interesting ways (mainly to dissociate them into characteristic fragments) and ejected in a manner to generate a mass spectrum.

Although QITs and QMFs were described at approximately the same time, the QMF initially achieved greater popularity as an analytical device. Two major discoveries changed the usage of the QIT. First, it was found that inclusion in the trap of a higher pressure (10^{-3} torr) of low molecular weight gas improved mass resolution and sensitivity. Second, the development of the mass-selective ejection, or mass-instability scan function, improved QIT scanning. With no DC voltage (i.e., along the *x*-axis) and a low RF voltage, ions of all *m/z* are stored in the QIT field. By increasing the RF voltage, ions of increasing *m/z* become axially unstable and leave the QIT sequentially by *m/z*. The ions leaving the QIT through one endcap are detected by an external electron multiplier. An additional improvement to the sensitivity of the QIT was the application of an axial modulation waveform to the endcap electrodes. This oscillating voltage improved the efficiency of ion ejection from the trap and improved mass resolution. All of these features and automatic gain control have been incorporated into the Thermo Finnigan PolarisQ GC/MS and the Varian 2000 series GC/MS systems.

In addition to the oscillating voltage mode of operation, the QIT is capable of operation in other modes. For example, the QIT can also be operated in a mass-selective storage mode. This mode of operation is similar to the QMF and involves selecting RF and DC conditions such that only ions of one mass are stored in the QIT at any time.

When interfaced with a gas chromatograph, confinement of all the ions and neutrals emerging from the GC column in the QIT results in two problems. First, the ions in the trap repel each other, disturbing the electrical field generated by the electrodes. This is called *space charge* and results in mass misassignments and a reduced dynamic range. Automatic gain control was introduced to resolve the mass accuracy problem. It monitors the number of ions in the trap in a prescan, then adjusts ionization time for the analytical scan so a targeted number of ions is formed. The dynamic range of QIT nevertheless remains inferior to a QMF, and for many applications, the QMF remains the better instrument for quantitative analysis.

The second problem is that ion-ion or ion-neutral reactions can occur. Reactions (e.g., proton transfer) result in high abundance of protonated molecular ions in the mass spectrum. Thus QIT can be disadvantageous for determining chemical composition in manual spectral interpretation, because the presence of the $(M + 1)^+$ ion tends to confuse the interpretation. Library spectral matching, however, is not affected if the spectral matching algorithm reflects the unique features of the QIT spectrum. An external ionization source with ion injection into the QIT is an alternative solution, because only ions are present in the trap (i.e., neutral analyte molecules that could participate in ion-molecule reactions are not present). The Thermo Finnigan PolarisQ GC/MS is an example of such an instrument.

For ion traps interfaced to HPLC via ESI, external sources are absolutely essential because the electrospray process cannot be carried out inside the trap. The Thermo Finnigan LCQ series ion traps and the Bruker Daltonics Esquire are examples of such instruments.

The storage capabilities of the QIT also change the practical aspects of monitoring selected ions. Because ions do not transiently pass through the QIT, as they do in a QMF, there is no opportunity to focus one ion on the detector and accumulate signal for a specified period of time (dwell time). Instead, the storage capabilities of the QIT can be used to increase the numbers of specific ions in the trap while ejecting unwanted ions. This is known as selected ion storage (SIS). Ions of different mass oscillate radially and axially at a specific frequency, called the *secular frequency*, which depends on the QIT geometry, the RF voltage, and RF frequency. By applying a voltage to the endcap electrodes at the same frequency as the secular frequency, ions of that mass efficiently absorb energy. They also become energetic

enough to escape the trapping field. Selective ejection of unwanted ions is achieved by using various combinations of waveforms applied to the endcaps or a combination of waveforms with RF voltage changes on the ring electrode. Basically, any voltage change combination that keeps the ion of interest within its stability envelope while making all other ion trajectories unstable can be used. This diversity, however, makes comparison of SIS techniques difficult. Desired ions stored in the QIT are ejected by using the mass-instability scan function.

The ability to apply customized waveforms to the QIT, together with the fact that ions are trapped and therefore can be subjected to different treatment over a period of time, makes the QIT one of the most versatile of mass spectrometers, rivaled only by the ICR mass spectrometer. This is most strongly evident in tandem mass spectrometry (MS/MS and related techniques), which will be discussed separately. It should be noted here, however, that multiple stage MS/MS experiments (MS/MS/MS . . . , or MS^n) experiments are readily performed in ion traps.

The ability to store ions also has other distinct advantages. Using the mass-selective ejection scan approach, mass resolution on the QIT is inversely proportional to the scan rate. By slowing the scan rate, mass resolution similar to that achieved in sector instruments has been achieved. For example, this technique has been used to determine the charge state of multiply charged protein ions generated by ES ionization. In commercial instruments, higher mass resolution is available over a limited mass range in the Bruker Esquire and Thermo Finnigan LCQ mass spectrometers. Unfortunately, one of the advantages normally conferred by high resolution—exact mass capability—is not fully realized by this technique.

The QIT also shares some advantages with TOF-MS. In particular, ion trap mass spectrometry is known for high sensitivity. Furthermore, sampling is decoupled from scanning, so there is no mass spectral peak skewing in GC-MS and HPLC-MS.

Linear Ion Trap. This is a RF ion trap that is based on a modified linear QMF. Rather than being a pass-through device as in a normal linear QMF, electrostatic fields are applied to the ends to prevent ions from exiting out the ends of the device. Thus being trapped, ions can be manipulated in many of the same ways as in a QIT. An advantage of the linear quadrupole trap is that the trapping field can be turned off at will and the device operated as a normal QMF. Thus a single device combines most of the features of a QIT and QMF and is extremely versatile. Commercial triple quadrupole mass spectrometers are being offered in which the third quadrupole is modified to function as a linear trap. The exploration of the capabilities of the linear ion trap is a very active field of research, and one can expect many new capabilities to be discovered in the next few years. Both Thermo Finnigan and Applied Biosystems/MDS Sciex market linear QIT.

Ion Cyclotron Resonance. The ICR-MS excels in high-resolution and high-mass accuracy measurements. Measurements at resolution exceeding 1 million are not unusual, and sub-ppm mass accuracy is being explored by some investigators. ICR is a trapping technique and shares many of the advantages of RF ion traps; however, there are even more ways to manipulate ions in a ICR-MS than in QIT, and MS^n measurements are easily done with a ICR-MS. Sensitivity of a ICR-MS is generally high. Furthermore, sampling is decoupled from spectral acquisition, so there is no peak skewing in chromatographic experiments, a feature that ICR shares with TOF and QIT.

An ICR-MS is based on the principle that ions immersed in a magnetic field undergo circular motion (cyclotron motion). A typical ICR-MS uses a high-field (3 to 12 tesla) superconducting magnet. Within this field and within a high vacuum is mounted a "cell" typically composed of six metal electrodes, arranged as the faces of a cube. Ions are suspended inside the cell and undergo cyclotron motion, which keeps ions from being lost radially (the radial direction being defined as perpendicular to the magnetic field lines). A low (~1 V) potential is applied to the endcaps to keep ions from leaving the trap axially. Thus the combination of electric and magnetic fields keeps ions confined within the cell.

Each m/z is associated with a specific cyclotron frequency. The relationship is given by:

$$\frac{m}{z} = \frac{B}{2\pi f} \tag{2}$$

where B is the magnetic field strength and f is the frequency. This equation is an approximation to the frequency of an ion's orbital motion in the magnetic field. The frequency is shifted slightly because of the trapping voltage. For presentation purposes, this small shift in frequency is ignored here. This equation is independent of ion kinetic energy, and this fact, combined with the fact that frequency can be measured very precisely, means that very accurate m/z measurements can be performed by an ICR-MS.

The side electrodes of an ICR cell are used for ion detection. The electrodes are used in pairs, with opposite electrodes making a pair. To one pair of electrodes is applied a transient waveform, typically containing a superposition of many frequencies within the tens to hundreds of kHz range. This excites the cyclotron motion of ions in the cell, but only if the waveform contains frequency components matching the cyclotron frequency. Before excitation the diameter of an ion's cyclotron orbit is small, and the phases are random. After excitation the diameter is large. Furthermore the orbital motion of the ions of a given m/z is now synchronized, meaning that ions orbit in phase with each other. This orbital motion induces an electrical signal in the other pair of electrodes. Following the excitation step, the induced signal is amplified electronically and recorded in the data system computer. If there are a variety of ions of different

m/z present in the cell, the recorded waveform is a complex superposition of many frequencies. A mathematical operation, known as a Fourier transform (FT), is applied to this signal. Each *m/z* value present in the sample produces a peak in the transformed signal. The transformed function is a frequency spectrum of the signal. The frequency of a peak is related to *m/z* according to the preceding equation. Thus the frequency spectrum of ions in the cell is equivalent to the mass spectrum of the sample. The actual mass spectrum is obtained by changing the *x*-axis from frequency to mass using the equation presented above. Because of the frequent use of FT in ICR, the technique is often referred to as FT-ICR or FTMS.

The most notable feature of the process described above is that ions are not destroyed by the detection process. Therefore ions can be further manipulated after detection. The simplest example is the remeasurement of ions (i.e., repeating the excite and/or detect sequence to obtain another mass spectrum of the same group of ions). More complex manipulations include multiple stages of MS/MS. The facts that ions are detected nondestructively and that they are trapped in a region of space mean that very complex sequences of ion manipulations are possible, making FT-ICR instruments the most versatile of all mass spectrometers.

Like the QIT, ionization in the FT-ICR may be performed either internally or externally to the cell. For several reasons, external ionization has become the technique of choice. External ionization allows the use of virtually any ionization method, and commercially available instruments are typically designed as general purpose instruments incorporating interchangeable ion sources. All three major suppliers of FT-ICR instruments (IonSpec, Bruker Daltonics, and Finnigan) offer external sources.

Although having many advantages, ICR-MS has several disadvantages including (1) high instrument cost; (2) very demanding site requirements, both in terms of space and in terms of access restrictions; (3) it uses a high-field superconducting magnet, and its magnetic field introduces safety concerns, such as flying iron objects, and practical concerns, such as the erasing of credit cards and other magnetically encoded strips; (4) cost of operation, care, and maintenance is high because the instruments consume liquid helium, and they must never be allowed to go dry; (5) a highly skilled operator level is necessary to operate it. Consequently, these instruments have yet to make an impact in the clinical lab, though they could well become important in the future if some of their disadvantages are overcome.

Tandem Mass Spectrometers

Tandem mass spectrometry, or mass spectrometry/mass spectrometry (MS/MS), is rapidly becoming an important technique in clinical laboratories where it is mainly used for quantitative analysis of routine samples.[16] However, it is also excellent for structural characterization and compound identification, and is therefore useful for exploratory work, even when a final assay may be based on a different technology, such as an immunoassay. The most important feature of this technique is very high selectivity together with good sensitivity. When coupled with the added selectivity of an HPLC, interferences in a well-designed MS/MS assay (and particularly an HPLC-MS/MS assay) are very low. Because of its low interference rate, low consumable cost (as with most MS methods) and high sample throughput rates, more and more clinical labs are purchasing and using tandem mass spectrometers.

The physical principle of tandem mass spectrometers is best understood by considering beam-type instruments, either a magnetic sector or a quadrupole mass spectrometer. Two mass spectrometers are arranged sequentially, with a "collision cell" placed between the two instruments. The first instrument is used to select ions of a particular *m/z*, called either the "parent ion" or "precursor ion." The parent ion is directed into the collision cell, where ions collide with background gas molecules and are broken into smaller ions. These have been traditionally referred to as "daughter ions" to emphasize the fact that they are derived from the parent ion, though the terminology "product ions" is now preferred by some.[32] The second mass spectrometer acquires the mass spectrum of the daughter ions.

There are a variety of scan functions possible with tandem mass spectrometers. In practice, a product ion scan involves setting the first mass spectrometer, MS1, to select a given *m/z* and scanning through the full mass spectrum of product ions. This scan function is often used for structural characterization. A precursor ion scan reverses this relationship, with the second mass spectrometer, MS2, set to select a specific daughter ion, and MS1 is scanned through the spectrum. The peaks in the parent ion scan tell us which parent ions produce a specific product ion, a capability that is often used to analyze for specific classes of compounds. For example, acylcarnitines are often analyzed by searching for the precursors to the *m/z* 85 product ion. In a constant neutral loss scan, the two mass spectrometers are scanned synchronously, with a constant *m/z* offset between parent and product ion. This scan indicates what ions lose a particular neutral fragment. For example, an offset of 18 *m/z* units would select for ions losing H_2O in the dissociation process. Another scan function is multiple reaction monitoring or MRM. This is not actually a scan function at all but consists of a series of parent/product ion pairs, with the mass spectrometer set to jump through the table of pairs in a cyclical fashion. This is primarily used for quantitative analysis of a few selected target compounds and is a close analogue to SIM monitoring used in GC-MS.

The key to the high selectivity of MS/MS is that it characterizes a compound by two physical properties, parent ion mass and daughter ion mass, rather than a single property. If combined with a chromatographic separation, the retention time is then added to the characterization, and the analytes are characterized by three physical properties. This

high selectivity eliminates that vast majority of potential interferences.

As with single-stage mass spectrometers, tandem mass spectrometers can be roughly categorized as beam-type instruments and trapping instruments. The most popular beam-type instrument is the triple quadrupole. In this instrument the first quadrupole (Q1) functions as MS1, and the third quadrupole (Q3) functions as MS2. Between these two quadrupoles is another quadrupole, Q2, which functions as the collision cell. The pressure is raised in Q2 (e.g., greater than 10^{-3} torr) to the point that ions traversing Q2 undergo several collisions, leading to dissociation. Q2 is operated as an "RF-only" quadrupole, ideally passing all ions regardless of *m/z*, although in reality the passband would typically cover a ~10:1 *m/z* range.

Two magnetic sector instruments have also been operated in tandem, with a collision cell placed between the two instruments. These instruments permit high resolution selection of both parent and product ions. However, these instruments are now rarely used as they are expensive and cumbersome to operate. Double focusing mass spectrometers can also be used as tandem mass spectrometers by a technique known as "linked scanning." A product ion scan by linked scanning involves low resolution for MS1 and high resolution for MS2.

Another technological development in tandem mass spectrometry is the combination of two TOF mass spectrometers, TOF/TOF. These instruments have excellent sensitivity and throughput for MALDI-MS/MS and are especially suited for proteomics research. However, these instruments are unable to perform true precursor ion scans or constant neutral loss scans. The Bruker Daltonics ultraflex and Applied Biosystem 4700 proteomics analyzer are examples of this type of instrument. Such instruments have yet to make an impact in clinical chemistry.

So-called hybrid mass spectrometers include a combination of two different types of mass spectrometers in a tandem arrangement. The combination of a magnetic sector mass spectrometer with a quadrupole mass spectrometer was an early instrument of this type. More popular is the combination of a quadrupole for MS1 and a TOF for MS2. As with TOF/TOF, these instruments are presently used mainly for proteomics research but could eventually find applications in the clinical lab. These instruments are unable to perform true precursor ion scans or constant neutral loss scans. Commercial examples of this type of instrument include the qTOF by Waters Micromass and the QSTAR by Applied Biosystems/MDS Sciex.

Trapping mass spectrometers can also be used as tandem mass spectrometers. Unlike beam-type instruments, which are referred to as "tandem in space," trapping mass spectrometers are "tandem in time," meaning that ions are held in one region of space while the parent ion is selected and dissociated and the daughter ion analyzed sequentially in time. The ability to perform tandem mass spectrometry is inherent in the design of trapping mass spectrometers. Generally, little or no additional hardware is required, with tandem capability supplied via a software change. Both QIT and ICR instruments are capable of tandem mass spectrometry. These instruments are capable of multiple stages of mass spectrometry. Thus product ions may be further dissociated to produce another generation of product ions (MS/MS/MS or MS^3). In principle any number of dissociation stages may be performed. This capability finds its greatest use in structural characterization, such as the sequencing of peptides, and is less useful for quantitative analysis. Trapping designs are extremely versatile, but unlike triple quadrupoles they are unable to perform true precursor ion scans or constant neutral loss scans.

Detectors

With the exception of an ICR-MS, nearly all mass spectrometers use electron multipliers for ion detection. There are three main classes of electron multipliers: discrete dynode multipliers, continuous dynode electron multipliers (CDEM), also known as channel electron multipliers (CEM), and microchannel plate (MCP) electron multipliers, also known as multichannel plate electron multipliers. Though different in detail, all three work on the same physical principle. An additional detector used in mass spectrometers is the Faraday cup.

Discrete Dynode Multipliers

Figure 7-12 presents a conceptual diagram of the operation of a discrete dynode electron multiplier. When an ion strikes the first dynode, it causes the ejection of one or more electrons ("secondary electrons") from the dynode surface. The electron is accelerated toward the second dynode by a voltage difference of ~100 V. Upon striking the second dynode, this electron causes the ejection of additional electrons, typically 2 or 3 in number. The second group of electrons is then accelerated toward the third dynode, and upon striking the third dynode, causes the ejection of several more electrons. The process is repeated through a chain of dynodes, num-

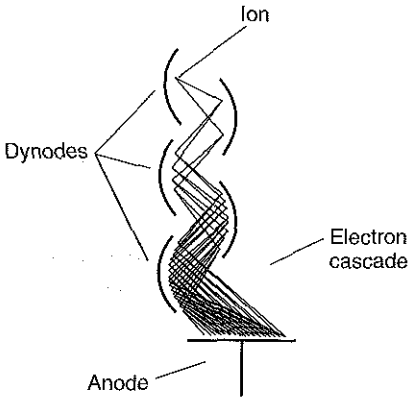

Figure 7-12 Discrete dynode electron multiplier showing dynode structure and generation of electron cascade.

bering between 12 and 24 for most designs. The cascade process typically produces a gain of 10^4 to 10^8, meaning that the generation of one electron at the first dynode produces a pulse of 10^4 to 10^8 electrons at the end of the cascade. The duration of the pulse is very short, typically less than 10 nanoseconds.

Continuous Dynode Electron Multiplier

CDEMs, sometimes called CEMs, work on the same principle as discrete dynode electron multipliers but differ in their physical construction. The set of dynodes of a discrete dynode electron multiplier is replaced by a single continuous surface. Usually the continuous surface takes the form of the inside of a tube, flared at the entrance end. The surface of the tube contains an electrically resistive layer. A voltage gradient is generated down the length of the tube by applying a voltage difference between the entrance and exit ends. The voltage gradient in the CEM takes the place of the discrete voltage drops between the dynodes of the discrete dynode electron multiplier. The resistive layer also serves as the secondary electron emitter. The CDEM is generally fabricated from a specialized glass, and the resistive surface is formed by chemically treating the surface of the glass. DeTech, Burle, and K and M Electronics all market a variety of CDEMs.

Microchannel Plate Electron Multipliers

MCPs operate on the same principle as CDEMs. A microchannel plate is essentially a monolithic array of miniaturized CDEMs fabricated in a single wafer or disk of glass. The disk contains pores extending from the upper surface to the lower surface. These pores are known as channels and perform the same function as the interior of the tube in a CEM, but in contrast to a typical CEM, the entrance ends of the channels are not flared. The channels are typically 3 to 30 micrometers in diameter depending on the design. The length of the channels is set by the thickness of the disk, typically 200 to 1000 micrometers. Microchannel plates can be fabricated in areas measured in cm^2, and because the disk-shaped profile forms a nearly flat stopping surface for ions, they are ideal detectors for TOF mass spectrometers. Burle and Hamamatsu are the major suppliers of these devices.

Faraday Cup

The Faraday cup is a simple electrode that intercepts the ion beam directly. This current is then amplified using electronic amplifiers. Because the Faraday cup measures signal intensity directly, rather than indirectly (as in saturation-prone electron multipliers) it provides an absolute measure of ion current and is also useful when signal levels are too high for electron multiplier–based detection. Some instruments use both electron multiplier– and Faraday cup–based detection to provide for extended dynamic range, a capability that can be especially useful for elemental analysis of trace metals in samples.

Computer and Software

Because of their mass resolution capabilities, scanning functions, ability to automatically switch from positive to negative ionization modes, and speed with which multiple *m/z* signals can be monitored, modern MS instruments generate enormous amounts of raw data. In addition, the use of MS, in such areas as proteomics, biomarker discovery, synthetic combinatorial chemistry, high throughput drug discovery, pharmacogenomics, toxicology, and therapeutic drug monitoring requires that manufacturers provide sophisticated computers and software programs.

In toxicology laboratories one important function of the data system is library searching to assist in compound identification. There are several commercial libraries, including the Wiley Registry of Mass Spectral Data, the NIST Mass Spectral Database, and the Pfleger, Maurer, and Weber drug libraries. In addition, many laboratories generate their own libraries. The quality and quantity of available spectra, the search algorithm, and whether condensed or full spectra are searched are all important in spectral matching. There are several library search algorithms available, the most popular being probability-based matching and the dot product matching approach modified by the NIST. Both approaches provide an assessment of match quality between the observed spectra and the library spectra.

In proteomics and biomarker discovery, complex mass spectra from single proteins, protein mixtures, or protein digests are obtained. Data systems exist that aid in characterization of spectral data to identify such properties as intact protein mass, amino acid subsequences, and post-translational modifications. Fragmentation information can also be compared with peptide databases to identify structural mutations that may be present.

Software programs are also available to locate and identify components in complex chromatographic separations. Deconvolution protocols have been developed that identify and characterize the mass spectra of co-eluting compounds. In some cases two separate sets of chromatographic data can be compared to evaluate similarities or unique differences (e.g., controls versus disease state).

CLINICAL APPLICATIONS

Mass spectrometers coupled with gas and liquid chromatographs (GC-MS and LC-MS) result in versatile analytical instruments that combine the resolving power of the chromatographs with the exquisite specificity and sensitivity of a mass spectrometer. Such instruments are powerful analytical tools that are used by clinical labs to identify and quantify organic analytes. They provide structural and quantitative information in real time on individual analytes as they elute from a chromatographic column. These coupled techniques are very sensitive and only nanogram or picogram quantities of an analyte are required for analysis. Specific applications of these coupled instruments are found in Chapters 33 and 34.

MALDI-TOF mass spectrometers and SELDI and ICP ionization techniques have also enhanced the analytical capabilities of mass spectrometers. In addition, an important application of MS is its use as the primary analytical tool in the rapidly developing and expanding field of proteomics. Also included in this section is a discussion of ion suppression and how it relates to the analytical capabilities of mass spectrometers.

Gas Chromatography-Mass Spectrometry

GC-MS has been used for the analysis of biological compounds for several decades. This technique is used by the U.S. National Institute of Standards and Technology as a definitive method to qualify standard reference materials and to assign certified values to many clinical analytes, including cholesterol, glucose, creatinine, and urea nitrogen (see Chapter 1). One of the most common applications of GC-MS is in drug screening for clinical or forensic purposes (see Chapter 34). Many drugs have relatively small molecular weights and nonpolar and/or volatile properties, which make these compounds particularly suitable for analysis by GC. Electron ionization with full-scan mass detection is the most widely used approach for comprehensive drug screening. Identification of unknown compounds can be achieved by comparison of their full mass spectrum with a mass spectral library or database. Numerous state and federal agencies mandate that only GC-MS be used to confirm the presence of drugs in samples presumptively found to be positive by immunochemical analyses.

GC-MS has many applications beyond drug screening. Numerous xenobiotic compounds can be readily analyzed by GC-MS. Applications for anabolic steroids, pesticides, pollutants, and inborn errors of metabolism have been described.[46,63,81]

One important limitation to GC-MS is the requirement that compounds be sufficiently volatile to allow transfer from the solid phase to the mobile carrier gas and thus elute from the analytical column to the detector. Although many biological compounds are amenable to chromatographic separation with GC, there are a large number of compounds that are too polar or too large in size to be analyzed with this technique.

Liquid Chromatography-Mass Spectrometry

Compared with gas chromatographs, it is more difficult to interface liquid chromatographs with mass spectrometers because the analytes are dissolved in a liquid rather than a gas. As discussed previously, several interface techniques have been developed for coupling a liquid chromatograph to a mass spectrometer, which has allowed HPLC-MS and HPLC-MS/MS to be successfully applied to a wide range of compounds. In theory as long as a compound can be dissolved in a liquid, it can be introduced into an HPLC-MS system. Thus polar and nonpolar analytes and large molecular weight compounds, such as proteins, can be monitored using this technique.

An important area where tandem MS is used clinically is screening and confirmation of genetic disorders and inborn errors of metabolism (see Chapter 55).[17] The ability to analyze multiple compounds in a single analytical run makes this technique an efficient tool for screening purposes. Electrospray tandem MS has become the recognized reference method for carnitine and acylcarnitine analysis to identify organic acidemias and fatty acid oxidation defects.[15,34] It is also becoming more recognized as an excellent tool for the analysis of amino acids. In the case of carnitine and amino acid analysis, these compounds vary widely in their polarity, which creates problems with consistency of response factors. To address this, most procedures employ a butyl ester derivatization of the carboxyl group to force cationic character upon the amino acids and thus yield similar ionization efficiencies for these compounds.[13] Direct flow injection analysis works well for these screens but can have the limitation of a lack of specificity for isobaric amino acids, such as leucine, isoleucine and hydroxyproline, or isobutyrylcarnitine and butyrylcarnitine. In these cases chromatographic separation is required before tandem MS.[13]

Other clinically relevant compounds that are amenable to HPLC-MS analysis include all of the major immunosuppressants, antiretrovirals, homocysteine, biogenic amines, methylmalonic acid, and hemoglobin variants.*

MS is widely used in pharmaceutical development via the process of "high throughput screening." To most efficiently use available resources, research labs synthesize large sets of diverse organic compounds or derivatives of starting core structures. This is often called combinatorial chemistry. The same process of identification is also applied to natural products as pharmaceutical candidates. These vast sets of compounds must be screened for unique structure and evaluated for potential as candidates for further study. This requires high throughput screening of large mixtures or isolates containing many compounds. MS has become the most efficient technique to identify these types of compounds. One example is the use of HPLC-MS to identify new taxanes in botanical extracts as effective anticancer agents.[87]

Important to investigating therapeutic approaches is the recognition of target protein receptors that may be associated with selected diseases. This information can facilitate structure-based approaches to drug design and ideally selective activity toward specific targets. The challenge in drug design has been how to test whether a compound binds to a protein receptor and whether this binding modulates the structure of the receptor. Size exclusion chromatography coupled with MS can be used to help answer these types of questions. After incubating a drug with protein(s), small size

*References 6, 25, 51, 52, 58, 90.

exclusion columns (e.g., Sephadex G25 or Bio-Gel P6) are used to separate free and bound drug. Small unbound molecules diffuse into particle pores and are retained, and larger drug-protein complexes are not retained and elute from the column. The small columns are often placed into a centrifuge and centrifugal force used to speed up the separation. The eluted drug-protein complexes are then analyzed by HPLC-ESI-MS to identify the structural properties of those compounds that effectively bind to the protein target.[82] This process can also be combined with nuclear magnetic resonance (NMR) to investigate bound complexes. NMR chemical shift perturbations can be used to help identify the binding site on a protein and whether this is specific or nonspecific binding.[65] Similar experiments can be performed to evaluate cellular absorption and/or permeability and intestinal cytochrome P4503A4 metabolism using Caco-2 cell monolayers,[19] and inhibition of metabolism with mixtures of hepatic microsomal enzymes, where probe substrates for each enzyme are used to monitor inhibition of multiple enzymes in one assay.[8]

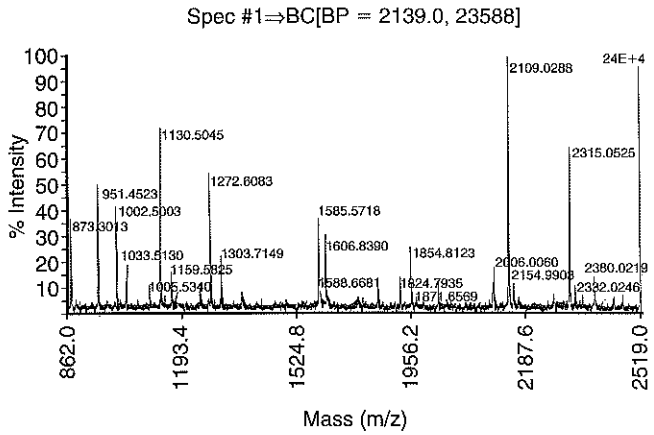

Figure 7-13 An example of a MALDI-TOF spectrum showing peptides generated in a tryptic digest of a spot cored from a 2-D, SDS-PAGE gel. The 16 most abundant *m/z* were submitted to MS-FIT for searching against the nonredundant database. The top result for this search is shown in Table 7-1.

MALDI-TOF Mass Spectrometry

MALDI-TOF has been used to analyze thousands of different classes of compounds. The major considerations for this ionization technique are the ability to co-crystallize with one of the hundreds of matrix molecules available and the ability to form positive or negative ions or a charged adduct that is measured in the mass analyzer. Uses generally fall into one of three broad categories: (1) detection of a particular compound(s), (2) identification of a protein(s), or (3) identification of an organism.

The detection of phosphatidylcholine and its digestion products[71] is a good example of detection of a specific compound and in this case the monitoring of the progress of an enzymatic reaction. These small molecules can be detected as positive ions and readily retain sodium adducts. In addition to simple identification, the authors also monitor progression of the phospholipase digestion. Although MALDI should not be considered quantitative, the use of relative signal-to-noise ratios can be used to monitor the progression of this digestion (or reaction). The main point of small molecule detection by MALDI is that the molecule must co-crystallize with the matrix (and not react), be able to be desorbed back out of the matrix, and form an ion or adduct that can be detected. Although MALDI is simple and fast, other MS and non-MS techniques are often as good or better for small molecule analysis.

MALDI-TOF is often used to determine the identity of proteins through peptide mass fingerprinting (PMF). This technique has been used to identify a large number of 2-D gel spots for the bacterial pathogen *Pseudomonas aeruginosa*.[77] The procedure generally involves in-gel tryptic digestion followed by accurate mass measurement of the peptides. The generated mass list is then compared with theoretical tryptic masses for proteins in a database (Figure 7-13 and Table 7-1). The procedure works best for organisms with complete and annotated genomes. The procedure is very rapid, under 2 minutes per sample, because 100 or greater samples may be automatically processed and deposited on a single MALDI target plate. In the above example,[77] the group rapidly identified a large number of proteins that were expressed differently between laboratory and pathogenic bacteria. In addition, it was found that some proteins were listed as "hypothetical," meaning previously undescribed or confirmed to be expressed, and that theoretical molecular weights and/or isoelectric points (pIs) in some cases were extremely different from those measured in the gel, indicating possible terminal clipping and/or posttranslational modification. These observations are extremely useful in targeting areas of focus given the large amount of data generated by this technique.

The third area that MALDI-TOF is emerging in is identification of organisms, such as bacteria. A method has been described that attempts to identify bacteria by fingerprinting proteins that were extracted using gentle conditions.[91] The basis of this technique is that different bacteria should express unique proteins in the 2 to 20 kDa mass range, allowing classification according to the protein mass fingerprint. Although the other two areas mentioned above are quite mature, this area is still under final development. The major problems[91] are a lack of actual protein mass information for various bacteria and a lack of investigation into different strains of the same bacteria. The protein mass fingerprints must be cataloged for each bacterium and determined to be completely reproducible for a given extraction method. Further, more work will have to be done on changes at the protein level among different strains or isolates of putatively the same bacterium.

TABLE 7-1 Example of Printout of Bacterial Identification Through PMF Using MALDI-TOF A Generated Mass List Is Compared With Theoretical Tryptic Masses for Proteins in a Database. Match Quality Is Used for Pathogen Identification.

SELDI Mass Spectrometry

Currently the area of greatest interest in SELDI analysis is its use for the discovery of biomarkers for disease. An excellent example is biomarker identification in breast cancer.[56] The basic premise is that diagnosis of disease state can be done by monitoring away from the actual site of disease—most often serum, urine, or cerebrospinal fluid. This study follows the basic technique that proteins are affinity purified from the biological fluid, and markers are identified based on a large difference in abundance between control and disease. These markers are not even identified in the early stages of the experiment. The power of the technology is the rapid identification of multiple, potential biomarkers that can be used in concert as a diagnostic tool—highly desirable over many current single biomarker tests.

ICP Mass Spectrometry

As noted earlier in the chapter, ICP-MS is used for the determination of trace elements in many types of samples (see Chapter 35).[5] However, it is known that the toxicity of an element may depend on the organic or inorganic state in which the element is present. In these cases it is more important to ascertain the concentrations of toxic species rather than the total concentration of the element. To extend the utility of this technique, GC and HPLC systems are now being coupled to ICP-MS to separate individual elemental species before ICP-MS analysis.[61]

Proteomics

The past 20 years have seen tremendous progress in genomics, with hundreds of genomes completed or near completion and many now parsed and annotated. However, this information has often failed to provide vast new understanding into cellular function—mainly because of the myriad changes that occur to the proteins produced from the genome throughout the life cycle of a cell. In the mid 1990s, MS came to the forefront of analytical techniques used to study proteins and the term proteomics was coined. Although the definition is still debated, proteomics in the largest sense encompasses knowledge of the structure, function, and expression of all proteins in the biochemical or biological contexts of all organisms.[45] In a more basic and practical sense, proteomics refers to the identification and quantitation of proteins and their posttranslational modifications in a given system or systems. This is a challenging task as every gene has potentially 100 or more distinct, chem-

ical protein isoforms. In addition, many other molecules (metals, lipids, etc.) interact with proteins in a noncovalent fashion. Therefore in a genome, such as human, there may be a repertoire of millions of "proteins" requiring identification and quantitation.

Two foundations are necessary to begin this daunting challenge. The first is the basic sequence expected for each possible protein in a cell (i.e., a completed genome). The second is instrumentation, currently advanced mass spectrometers that identify and quantitate protein isoforms in an automated fashion at very low limits of detection. Both foundations are now essentially in place, and the field of proteomics has leapt forward over the past several years. The goal above is far from complete, however, as considerable advances will have to be made before we truly examine all the proteins in a cell.

Currently, MS is routinely used to accomplish many tasks in proteomics. The most basic task is protein identification. The typical approach is known as the "bottom-up" method, where proteins are separated—either by gel electrophoresis or by solution-based methods—and then digested. The resulting enzymatic fragments are analyzed and used to identify the protein(s) present. This process is time consuming and has many pitfalls. Increasingly, much research has been devoted to analysis of mixtures of proteins. These mixtures can be from cellular compartments, tissue, or immunoprecipitations. Although solving many problems associated with analysis of proteins isolated by gels, this technique suffers one major drawback—complexity. Currently, both instrumentation and analysis software are not sufficiently advanced to easily identify all the proteins in truly complex mixtures. As a result, much emphasis has been placed on separation methods for proteins and/or peptides. Many groups have introduced methods to begin handling this level of complexity. The most popular approaches are subcellular fractionation, multidimensional chromatography, and affinity labeling and/or purification. By combining these approaches, several thousand protein species can routinely be identified. Obviously these numbers are better than "bottom-up" methods from gels, but they still fall far short of those necessary for complete proteomics.

Two last areas that have to be addressed are quantitation and de novo sequencing and/or posttranslational modifications. First, most identified proteins must be quantitated in relation to changes in cell state or cell type. Quantitation in MS for these purposes is relative, (i.e., standard condition to perturbed condition). Current techniques in this area are still in the development phase but generally involve labeling either a subset of peptides (isotope-coded affinity tagging) or all peptides (metabolic labeling). Although some problems exist with the labeling, the greatest—as with identification—involves the sheer complexity of the sample to be analyzed. The second problem is both separate and related. Posttranslational modifications clearly are the major control mechanism in cells. Mass spectrometry is unique as a technique that can both identify and precisely locate a modification. However, the software to automate this process lags far behind the ability to collect the data. What is lacking is software for de novo sequencing, which can interpret a mass spectrum with little or no user intervention, especially in the area of posttranslational modifications. Currently, most modified spectra are manually interpreted by highly skilled mass spectrometrists, adding days or even weeks of analysis time per sample. These two problems, in addition to sample complexity, will have to be solved before proteomics evolves into a mature field.

All of these issues are addressed in numerous papers every month in journals ranging from *Proteomics* to *Clinical Chemistry*. Although an exhaustive listing is impossible, there are several review or opinion references that represent good starting points for exploration into the rapidly changing world of proteomics.*

ANALYTICAL PROBLEM OF ION SUPPRESSION

Ion suppression results from the presence of less volatile compounds that can change the efficiency of droplet formation or droplet evaporation, which in turn affects the amount of charged ion in the gas phase that ultimately reaches the detector.[1,47] Sample matrix, co-eluting compounds, and cross talk can contribute to this effect. Ionization effects can theoretically occur in either the solution phase or the gas phase. For biological extractions, one cause of ion suppression is a change in the spray droplet solution properties caused by the presence of nonvolatile or less volatile solutes.[47] These nonvolatile materials (e.g., salts, ion-pairing agents, endogenous compounds, drugs, and/or metabolites) change the efficiency of droplet formation or droplet evaporation, which in turn affects the amount of charged ion in the gas phase that ultimately reaches the detector. Anions, such as phosphate or borate in buffers, can also neutralize the effective ionization of an analyte.

The presence of ion suppression, or other deleterious effects, can be evaluated via several experimental protocols. One involves comparison of (1) the instrument response for standards (including any internal standards) injected directly in mobile phase and (2) the same amount of compound spiked into preextracted samples.[62] The data for the standard in mobile phase provide a relative 100% response value. The data for the same amount of compound spiked into preextracted samples show the effect of sample matrix on MS response (ion suppression).

A second protocol involves postcolumn continuous infusion of compound into the MS detector.[7,38,68] The instrumental setup includes a syringe pump connected via a tee to the column effluent (Figure 7-14). Because the compound being tested is introduced into the mass detector at a constant rate, a constant electrospray ionization response should

*References 30, 42, 57, 72, 76, 86.

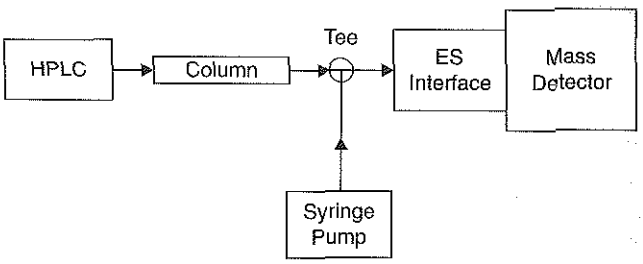

Figure 7-14 Postcolumn infusion system. Mobile phase or specimen extracts are injected into the HPLC system. The analyte being evaluated is continuously infused, postcolumn, and is mixed with the column effluent through a tee before entering the electrospray interface.

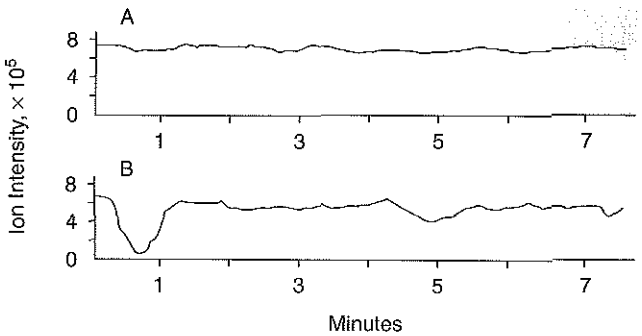

Figure 7-15 Infusion chromatograms for hypothetical analyte. **A,** Mobile phase injection. **B,** Serum liquid-liquid extract injection. These profiles illustrate that ion suppression can be greater than 90%, a recovery time may exist, and that suppression is not limited to the solvent front region. For a comprehensive presentation of these types of effects, the reader is referred to references 7, 38, and 68.

ideally be observed (Figure 7-15, *A*) if no ionization interferences occur when an extract from a biological specimen, such as serum, is injected into the HPLC portion of the instrument. In actuality it is common to see a suppression of the signal at the time point that corresponds to the void volume of the column (Figure 7-15, *B*). The degree of ion suppression and the recovery time to full response can vary from compound to compound[7] and from sample to sample and can also be dependent on the sample preparation method. Since endogenous compounds from the specimen matrix can continue to elute at any time during the chromatographic run, ion suppression is not limited to the column void. The observed degree of ion suppression can also be dependent on the concentration of the analyte being monitored,[89] which relates to the matrix/analyte ratio.

Another potential source of ion suppression is the effect that chromatographic ion-pairing agents may have on signal intensity. For example, trifluoroacetic acid (TFA) has been used in HPLC-UV analyses because it improves peak shape and retention times. Unfortunately, for MS analyses TFA also causes signal suppression and must be considered if this acid is used in the mobile phase. Being a component of the mobile phase this agent will continuously be introduced into the ESI interface, so that signal suppression may be observed throughout the entire chromatographic run.

There are several options that can be used to minimize or correct for ion suppression during HPLC-MS analysis. For ion pairing other weaker acids—such as acetic, formic, or hexafluorobutyric acid—may be successfully substituted for TFA in HPLC-MS analysis. The use of surface tension–lowering modifiers in the ESI source has also been reported to be successful when TFA is used as a mobile phase modifier.[27] The postcolumn addition of acids and solvent carriers to displace TFA from compounds and aid ionization has also been successfully employed. This is a process termed the "TFA fix."[2] It may also be possible to modify the chromatographic conditions so that the compound(s) of interest elute in a region where ion suppression is not observed.[4] Since many HPLC assays include an internal standard, another possibility is to modify chromatographic conditions such that the compound of interest and the internal standard co-elute.[48] The ion suppression for both compounds should be similar if the peaks chromatographically coincide, thus "correcting" for the degree of suppression.

Ion suppression is not limited to just HPLC-MS or ESI interfaces. For MALDI analysis, arginine-containing peptides have been reported to dominate the peptide pattern for protein digests,[50] the extent of which depends on the matrix used. The presence of ionic detergents, such as Triton X-100 and Tween 20, has also been shown to cause signal suppression in MALDI experiments, which can be countered by modifications to the matrix.[31]

CHAPTER 8

Principles of Clinical Enzymology*

Renze Bais, Ph.D., and Mauro Panteghini, M.D.

Enzymes are proteins with catalytic properties; clinical enzymology is the application of the science of enzymes to the diagnosis and treatment of disease. The principles of clinical enzymology will be introduced and discussed in this chapter. Individual topics include basic principles, enzyme kinetics, analytical enzymology, and diagnostic enzymology.

BASIC PRINCIPLES

This section begins with a discussion of enzyme nomenclature and is followed with discussions of enzymes as proteins and catalysts.

Enzyme Nomenclature

Historically, individual enzymes were identified using the name of the substrate or group upon which the enzyme acts and then adding the suffix *-ase.* For example, the enzyme hydrolyzing urea was ur*ease.* Later, the type of reaction involved was also identified, as in carbonic anhydrase, D-amino acid oxidase, and succinate dehydrogenase. In addition, some enzymes had been given empirical names such as trypsin, diastase, ptyalin, pepsin, and emulsin.

Because this combination of trivial common names and semisystematic names was found to be inadequate, the International Union of Biochemistry (IUB) appointed an Enzyme Commission (EC) in 1955 to study the problem of enzyme nomenclature. Its subsequent recommendations, with periodic updating, provide a rational and practical basis for identifying all enzymes now known and enzymes that will be discovered in the future (http://www.chem.qmw.ac.uk/iubmb/enzyme/).[9]

With the IUB system, a systematic and trivial name is provided for each enzyme. The systematic name describes the nature of the reaction catalyzed and is associated with a unique numerical code designation. The trivial or practical name, which may be identical to the systematic name but is often a simplification of it, is suitable for everyday use. The unique numerical designation for each enzyme consists of four numbers, separated by periods (e.g., 2.2.8.11). The number is prefixed by the letters *EC,* denoting *Enzyme Commission.* The first number defines the class to which the enzyme belongs. All enzymes are assigned to one of six classes, characterized by the type of reaction they catalyze: (1) oxidoreductases, (2) transferases, (3) hydrolases, (4) lyases, (5) isomerases, and (6) ligases. The next two numbers indicate the subclass and sub-subclass to which the enzyme is assigned. For example, these may differentiate the amino-transferring subclass from the phosphate-transferring category or the ethanol acceptor sub-subclass from that accepting acyl groups. The last number is the specific serial number given to each enzyme within its sub-subclass.

To illustrate how this system is used to name an enzyme, consider the enzyme creatine kinase that catalyzes the reaction:

$$\text{ATP} + \text{creatine} \rightleftharpoons \text{ADP} + \text{creatine phosphate}$$

*The authors gratefully acknowledge the original contributions by Drs. A. Ralph Henderson and Donald W. Moss, upon which portions of this chapter are based.

Its system number is:

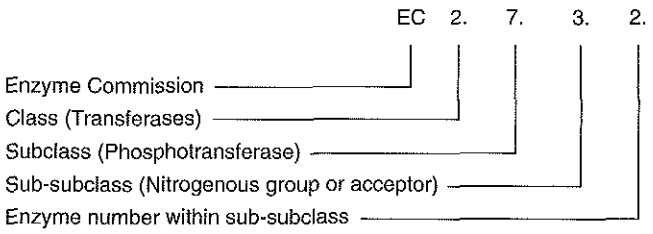

Table 8-1 lists some selected enzymes of clinical interest, identified by trivial, abbreviated, and systematic names and by their code numbers.

Although it is not recommended by the EC, it is a common and convenient practice to use capital letter abbreviations for the names of certain enzymes, such as ALT (formerly GPT) for alanine aminotransferase (EC 2.6.1.2). Other examples are AST for aspartate aminotransferase, LD for lactate dehydrogenase, and CK for creatine kinase (see Table 8-1).

Enzymes as Proteins

Basic Structure

All enzyme molecules possess the primary, secondary, and tertiary structural characteristics of proteins (see Chapter 20). In addition, most enzymes also exhibit the quaternary level of structure. The *primary* structure, the linear sequence of amino acids linked through their α-carboxyl and α-amino groups by peptide bonds, is specific for each type of enzyme molecule. Each polypeptide chain is coiled up into three-dimensional secondary and tertiary levels of structure. *Secondary* structure refers to the conformation of limited segments of the polypeptide chain, namely α-helices, β-pleated sheets, random coils, and β-turns. The arrangement of secondary structural elements and amino acid side chain interactions that define the three-dimensional structure of the folded protein is referred to as its *tertiary* structure. In many cases biological activity, such as the catalytic activity of enzymes, requires two or more folded polypeptide chains (subunits) to associate to form a functional molecule. The arrangement of these subunits defines the *quaternary* structure. The subunits may be copies of the

TABLE 8-1 Enzyme Commission (EC) Numbers, Systematic and Trivial Names, Together With Frequently Adopted Abbreviations of Enzymes of Major Diagnostic Importance

EC Number	Systematic Name	Trivial Name	Abbreviation
1.1.1.27	L-Lactate: NAD^+ oxidoreductase	Lactate dehydrogenase	LD
1.1.1.42	Threo-Ds- isocitrate: $NAD(P)^+$ oxidoreductase (decarboxylating)	Isocitrate dehydrogenase	ICD
1.4.1.3	L-Glutamate: $NAD(P)^+$ oxidoreductase (deaminating)	Glutamate dehydrogenase	GLD
2.3.2.2	(5-Glutamyl)-peptide: amino-acid 5-glutamyltransferase	γ-Glutamyltransferase	GGT
2.6.1.1	L-Aspartate: 2-oxoglutarate aminotransferase	Aspartate aminotransferase (transaminase)	AST
2.6.1.2	L-Alanine: 2-oxoglutarate aminotransferase	Alanine aminotransferase (transaminase)	ALT
2.7.3.2	ATP: creatine *N*-phosphotransferase	Creatine kinase	CK
3.1.1.3	Triacylglycerol acylhydrolase	Lipase	Lip
3.1.1.7	Acetylcholine acetylhydrolase	Acetylcholinesterase, true cholinesterase, cholineesterase I	—
3.1.1.8	Acylcholine acylhydrolase	Pseudocholinesterase, benzoyl cholinesterase, cholineesterase II (serum cholinesterase)	ChE (SChE)
3.1.3.1	Orthophosphoric-monoester phosphohydrolase (alkaline optimum)	Alkaline phosphatase	ALP
3.1.3.2	Orthophosphoric-monoester phosphohydrolase (acid optimum)	Acid phosphatase	ACP
3.1.3.5	5′-Ribonucleotide phosphohydrolase	5′-Nucleotidase	5NT, NTP
3.2.1.1	1,4-α-D-Glucan glucanohydrolase	Amylase	Amy
3.4.2.14		Trypsin	—
4.1.2.13	D-Fructose-1,6-bisphosphate D-glyceraldehyde-3-phosphate-lyase	Aldolase	ALD

same polypeptide chain (homomultimers [e.g., as the MM isoenzyme of creatine kinase, or the H_4 isoenzyme of lactate dehydrogenase]) or they may represent distinct polypeptides (heteromultimers). The biological activity, such as the catalytic activity of enzymes, is often found to be a property of the oligomeric molecule so that activity is usually lost under conditions in which the subunits separate from each other.

The application of physical methods, such as x-ray crystallography and multidimensional nuclear magnetic resonance (NMR) methods, has provided structural insights upon which theories of enzyme mechanisms have been built. Furthermore the tools of molecular biology, such as molecular cloning, have enabled the purification and characterization of enzymes that were previously only available in minute amounts. Molecular biology also enables the manipulation of the amino acid sequence of enzymes, and site-directed mutagenesis (substituting one amino acid residue for another) and deletion mutagenesis (elimination of sections of the primary structure) have allowed the identification of chemical groups that participate in ligand binding and in specific chemical steps during catalysis.

No feature of primary structure, such as repetition of particular amino acid sequences, is common to all enzyme molecules. However, considerable homologies of sequence are found between enzymes that appear to share a common evolutionary origin, such as the proteases trypsin and chymotrypsin, and similarities of sequence are even more marked among the members of a family of isoenzymes. The amino acid sequence in the immediate neighborhood of the active center of the enzyme (discussed later) is often closely similar in enzymes of related function (e.g., the *serine proteases* are so called because they all have this amino acid in the active center).

Enzyme molecules differ in the proportion of secondary-level structures—such as α-helices—they contain, although no enzyme molecule so far studied approaches the large proportion of α-helices found in myoglobin and hemoglobin. The tertiary structures of different types of enzyme molecules are as individually characteristic as their primary structures; nevertheless, some common features can be discerned at this structural level. Enzyme molecules are roughly globular in overall shape, with a preponderance of polar amino acid side chains on the outside of the molecule and nonpolar side chains in the interior. The ionizable residues in contact with the surrounding medium are responsible for many of the properties of the enzyme molecules in a solution, such as their migration in an electric field and their solubility. Covalent disulfide bridges may link different parts of the polypeptide chains in some enzyme molecules, but the three-dimensional structure is mainly stabilized by the large number of hydrophobic interactions that are formed between the nonpolar side chains in the interior of the molecule.

The biological activity of a protein molecule depends generally on the integrity of its structure. Any disruption of the structure is accompanied by a loss of activity, a process known as *denaturation.* If the process of denaturation is minimal, it may be reversed with the recovery of enzyme activity upon removal of the denaturing agent. However, prolonged or severe denaturing conditions result in an irreversible loss of activity. Denaturing conditions include elevated temperatures, extremes of pH, and chemical addition. Heat inactivation of most enzymes takes place at an appreciable rate at room temperature and becomes almost instantaneous in most cases above about 60 °C. The polymerases are an exception and retain activity at temperatures as high as 90 °C. Low temperatures are therefore used to preserve enzyme activity, especially in aqueous solutions, such as serum (see Chapter 21). Extremes of pH also cause unfolding of enzyme molecular structures and, except for a few exceptions, should be avoided when preserving enzyme samples. Addition of chemicals, such as urea and related compounds, disrupts hydrogen bonds and hydrophobic interactions so that exposure of enzymes to strong solutions of these reagents results in inactivation.

Isoenzymes and Other Multiple Forms of Enzymes

Isoenzymes are multiple forms of an enzyme that possess the ability to catalyze the enzyme's characteristic reaction but that differ in structure because they are encoded by distinct structural genes.* These enzyme variants may occur within a single organ or even within a single type of cell. The forms can be distinguished on the basis of differences in various physical properties, such as electrophoretic mobility or resistance to chemical or thermal inactivation. They often have significant quantifiable differences in catalytic properties. However, all the forms of a particular enzyme retain the ability to catalyze its characteristic reaction.

The existence of multiple forms of enzymes in human tissue has important implications in the study of human disease. The presence in different organs of isoenzymes with distinctive properties helps in understanding organ-specific patterns of metabolism, but genetically determined variations in enzyme structure between individuals account for such characteristics as differences in sensitivity to drugs and differences in metabolism, which manifest themselves as hereditary metabolic diseases. For diagnostic enzymology, the existence of multiple forms of enzymes, whether due to genetic or nongenetic causes, may provide opportunities to increase the diagnostic specificity and sensitivity of enzyme assays in body fluid samples.

Like other proteins, enzymes usually elicit the production of antibodies when they are injected into animals of a species other than those in which they originate. Even small structural differences between closely similar molecules, such as the members of a family of isoenzymes, are often sufficient to render them antigenically distinct, allowing antibodies to

*The IUB recommends that the term "isoenzyme" be restricted to forms that originate at the level of the genes that encode the structures of the enzyme proteins in question.[1]

be produced specific to a single type of molecule. The availability of enzyme-specific antisera opens up a wide range of methods in enzyme analysis, some of which—such as immunoassay—do not depend on the catalytic activity of the enzyme molecules. The availability of immunochemical methods has been particularly important in the analysis of isoenzyme mixtures.

Genetic Origins of Enzyme Variants

True isoenzymes are due to the existence of more than one gene locus coding for the structure of the enzyme protein. Many human enzymes (perhaps more than one third) are known to be determined by more than one structural gene locus. The genes at the different loci have undergone differential modifications during the course of evolution so that the enzyme proteins coded by them no longer have identical structures, although they are recognizably similar; in other words, they are isoenzymes. *Multiple-gene loci* have become disseminated throughout a whole species during the course of evolution, so that these genes and their resultant isoenzymes typically are present in all individuals of that species.

The multiple genes that determine a particular group of isoenzymes are not necessarily closely linked on one chromosome; they are often located on different chromosomes. For example, the structural genes that code for human salivary and pancreatic amylases both are located on chromosome 1, whereas the genes that code for mitochondrial and cytoplasmic malate dehydrogenase are carried on chromosomes 7 and 2, respectively. Among the enzymes of clinical importance that exist as isoenzymes because of the presence of multiple gene loci are lactate dehydrogenase, creatine kinase, α-amylase, and some forms of alkaline phosphatase.

A mechanism that results in an enzyme existing in molecular forms that differ from one individual to another is the existence of alternative alleles that are inherited according to Mendelian laws. These give rise to gene products with the same function. The isoenzymes that result from the existence of allelic genes are termed *allozymes*. The proportion of human gene loci subject to allelic variation is considerable, and the probability that individual human beings will differ to some degree in their isoenzyme patterns is correspondingly high.

The number of allelic variants and the frequency with which particular variants occur within the population vary considerably from one enzyme to another. For example, mutations at either of the two principal loci that determine human lactate dehydrogenase are extremely rare, but a high incidence of mutant alleles occurs at the single locus that determines the structure of placental alkaline phosphatase. More than 340 mutations in the glucose-6-phosphate dehydrogenase gene have now been identified on the X chromosome (up-to-date genetic information on this and other enzymes, can be obtained from the Online Mendelian Inheritance in Man (OMIM) database at http://www3.ncbi.nlm.nih.gov/Omim/searchomim.html). Some of these alleles are extremely rare, whereas others occur with appreciable frequency in particular populations or geographical locations. When isoenzymes, due to variation at a single locus, occur with appreciable frequency in a human population, the population is said to be *polymorphic* with respect to the isoenzymes in question.

Another category of multiple molecular forms can arise when enzymes are oligomeric and consist of molecules made up of subunits. The association of different types of subunits in various combinations gives rise to a range of active enzyme molecules. When the subunits are derived from different structural genes, either multiple loci or multiple alleles, the hybrid molecules so formed are called *hybrid isoenzymes*. The ability to form hybrid isoenzymes is evidence of considerable structural similarities between the different subunits. Hybrid isoenzymes can be formed in vitro, but they are also formed in vivo in cells in which the different types of constituent subunits are present in the same subcellular compartment.

The number of different hybrid isoenzymes that can be formed from two nonidentical protomers depends on the number of subunits in the complete enzyme molecule. For a dimeric enzyme, one mixed dimer (hybrid isoenzyme) can be formed. If the enzyme is a tetramer, three heteropolymeric isoenzymes may be formed (Figure 8-1). Examples of

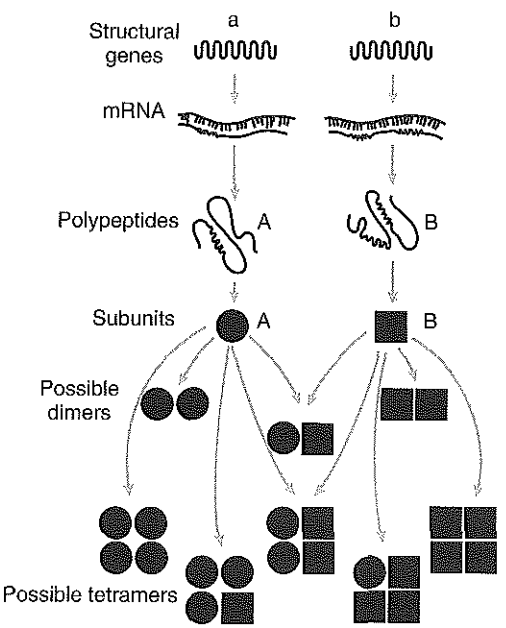

Figure 8-1 Diagram showing the origin of isoenzymes, assuming the existence of two distinct gene loci. When the active enzymes are polymers containing more than one subunit, hybrid isoenzymes consisting of mixtures of different subunits may be formed. One such isoenzyme can be formed in the case of a dimeric enzyme, such as creatine kinase, and three if the enzyme is a tetramer (e.g., lactate dehydrogenase). In both cases, two homopolymeric isoenzymes can also exist. *(From Moss DW. Isoenzyme analysis. London: The Chemical Society, 1979.)*

hybrid isoenzymes are the mixed MB dimer of creatine kinase and the three hybrid isoenzymes, LD-2, LD-3, and LD-4, of lactate dehydrogenase.

Nongenetic Causes of Multiple Forms of Enzymes

Many different types of posttranslational modification of enzyme molecules can give rise to multiple forms that are commonly known as *isoforms* (Figure 8-2). Several of these processes have been shown to cause the heterogeneity of various enzymes, either in living matter or as a result of changes taking place during extraction or storage.

Modification of the residues in the polypeptide chains of enzyme molecules can take place in living cells to give multiple forms. For example, removal of amide groups accounts for some of the heterogeneity of amylase and carbonic anhydrase (these enzymes also each exist as true isoenzymes). Modification can also take place as a result of extraction procedures. Many erythrocyte enzymes, including adenosine deaminase, acid phosphatase, and some forms of phosphoglucomutase, contain sulfhydryl groups that are susceptible to oxidation. In hemolysates, oxidation may be brought about by the action of oxidized glutathione, although in the intact cells, this compound is present in its reduced form. Thus, variant enzyme molecules with altered molecular charge may be generated.

Modifications affecting nonprotein components of enzyme molecules may also lead to molecular heterogeneity. Many enzymes are glycoproteins, and variations in carbohydrate side chains are a common cause of nonhomogeneity of preparations of these enzymes. Some carbohydrate moieties, notably *N*-acetylneuraminic acid (sialic acid), are strongly ionized and consequently have a profound effect on some properties of enzyme molecules. For example, removal of terminal sialic acid groups from human liver and/or bone alkaline phosphatase with neuraminidase greatly reduces the electrophoretic heterogeneity of the enzyme.

Aggregation of enzyme molecules with each other or with nonenzymatic proteins may give rise to multiple forms that can be separated by techniques that depend on differences in molecular size. For example, four catalytically active cholinesterase components with molecular weights ranging from about 80,000 to 340,000 are found in most sera, with the heaviest component, C_4, contributing most of the enzyme activity. Other enzyme forms are also occasionally present, but it appears that the principal serum cholinesterase fractions can be attributed to different states of aggregation of a single monomer.

A specific form of interaction between enzymatic and nonenzymatic proteins is the cause of unusual enzyme components noted when some samples of human plasma are fractionated by electrophoresis or chromatography. These components are due to a combination of apparently normal enzyme or isoenzyme molecules with plasma immunoglobulins. The enzyme-protein complexes ("macrocomplexes")

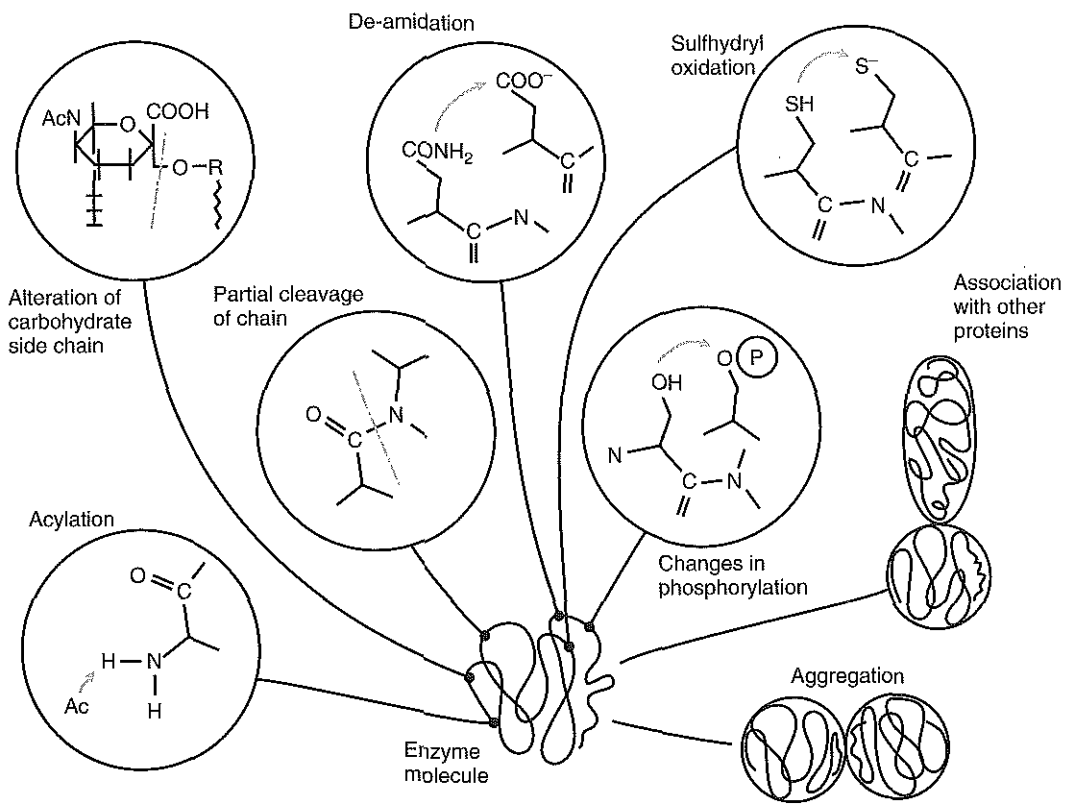

Figure 8-2 Nongenetic modifications that may give rise to multiple forms of enzymes. *(From Moss DW. Isoenzymes. London, Chapman & Hall, 1982.)*

thus formed may themselves be heterogeneous. Since the identification of "macroamylase," the first such enzyme-immunoglobulin complex to be identified, similar complexes have been observed involving lactate dehydrogenase, creatine kinase, alkaline phosphatase (ALP), and other enzymes.

A single polypeptide chain can in theory exist in an infinite number of different conformations. However, one specific conformation generally appears to be the most stable for any given sequence of amino acids, and this conformation is assumed by the chain as it is synthesized within the cell. Thus, the primary structure of the polypeptide chain also determines its three-dimensional secondary and tertiary structures. It is conceivable that in some cases there may be several alternative conformations ("conformers") of a single chain that are of nearly equal stabilities and therefore these alternative forms may coexist. This possibility was first suggested to account for the heterogeneity noted in preparations of the cytoplasmic and mitochondrial isoenzymes of malate dehydrogenase and has also been proposed as an explanation of the multiple electrophoretic zones of erythrocyte acid phosphatase. However, no multiple enzyme forms have been shown unequivocally to be due to conformational isomerism.

Distribution of Isoenzymes and Other Multiple Forms of Enzymes

The existence of multiple gene loci, and the isoenzymes derived from them, has presumably conferred an evolutionary advantage on the species and has thus become part of its normal metabolic pattern. Some of these adaptations are related to the division of function between and within different types of specialized cells and tissues. Thus, the distribution of isoenzymes is not uniform throughout the body, and wide variations in the activity of different isoenzymes are found at the organ, cellular, and subcellular levels. Tissue-specific differences are also found in the distributions of some multiple forms of enzymes that are not due to the existence of multiple gene loci. The tissue-specific distribution of isoenzymes and other multiple forms of enzymes provides the basis for organ-specific diagnosis through isoenzyme measurements.

Certain gene loci may be expressed almost exclusively in a single tissue, perhaps at a particular stage in development. In addition to the two gene loci that determine the two most common subunits of lactate dehydrogenase, a third locus is active only in mature testes. It determines the structure of a third type of subunit, X or C, which makes up a specific isoenzyme, LD-X or LD-C, found only in testes. The isoenzyme of ALP that occurs in the human placenta is the product of a single structural gene locus, which is distinct from the loci that specify the structures of other forms of ALP, and the product of the placental phosphatase locus is normally detectable only in the placenta.

A particularly striking example of the local expression of multiple gene loci is provided by distinct isoenzymes that occur exclusively in specific subcellular organelles. Differences between mitochondrial isoenzymes and their functionally analogous counterparts in the cytoplasm have been demonstrated in several cases (e.g., for aspartate aminotransferase and malate dehydrogenase.)

Changes in Isoenzyme Distribution During Development and Disease

Multiple gene loci and their resultant isoenzymes provide a means for the adaptation of metabolic patterns to the changing needs of different organs and tissues in the course of normal development or in response to environmental change. Pathological conditions may also be associated with alterations in the activities of specific isoenzymes.

The patterns of several sets of isoenzymes change during normal development in tissues from many species. For example, changes in the relative proportions of several isoenzymes are noted during the embryonic development of skeletal muscle. The proportions of the electrophoretically more cathodal isoenzymes, of both LD and CK, progressively increase in this tissue, until approximately the sixth month of intrauterine life, when the pattern resembles that of differentiated muscle. Smaller quantitative changes in isoenzyme distribution may continue to birth and into early postnatal life.

The liver also shows characteristic changes in the patterns of several isoenzymes during embryogenesis. In early fetal development, three aldolase isoenzymes, A, B, and C, together with the various hybrid tetramers, can be detected in extracts of liver. However, at birth as in the adult liver aldolase B is the predominant isoenzyme. Striking changes in the distribution of isoenzymes of alcohol dehydrogenase also occur in human liver during prenatal development.

The changes in isoenzyme patterns during development result from changes in the relative activities of gene loci within developing cells of a particular type (e.g., muscle cells). Other alterations in the balance of isoenzymes within the whole organism may derive from changes in the number or activity of cells that contain large amounts of a characteristic isoenzyme. An example of this is the increased number and activity of the osteoblasts, which are responsible for mineralization of the skeleton between the early postnatal period and the beginning of the third decade of life. The excess of ALP from the active osteoblasts enters the circulation, where its presence can be recognized by its characteristic properties and where it elevates the total serum ALP activity of young people above that of skeletally mature adults. An ALP from the liver also contributes to the total activity of this enzyme in normal plasma, and the amount of this isoenzyme in plasma shows a small, progressive increase with age. The reason for the latter age-dependent change is not known, but it may result from increased synthesis of the isoenzyme by hepatocytes in response to continuing exposure to inducing factors.

Certain diseases, such as the progressive muscular dystrophies, appear to involve a failure of the affected tissues to

mature normally or to maintain a normal state. Cancer cells show a progressive loss of the structure and metabolism of the healthy cells from which they arise. Therefore the pattern of isoenzymes of mature, differentiated tissue may be lost or modified if normal differentiation is arrested or reversed, and many examples have been reported of isoenzyme changes accompanying such processes.

The distributions of isoenzymes of aldolase, LD, and CK in the muscles of patients with progressive muscular dystrophy have been found to be similar to those in the earlier stages of development of fetal muscle. The isoenzyme abnormalities in dystrophic muscle have been interpreted as a failure to reach or maintain a normal degree of differentiation. Isoenzyme patterns in regenerating tissues may also show some tendency to approach fetal distributions. This tendency may result from relaxation or modification of control systems in rapidly dividing cells and may account for some of the isoenzyme changes noted (e.g., in muscle in acute polymyositis).

Reemergence of fetal patterns of isoenzyme distribution is also a feature of malignant transformation in many tissues. This phenomenon was first studied extensively in the case of lactate dehydrogenase isoenzymes. Malignant tumors in general show a significant shift in the balance of isoenzymes toward the electrophoretically more cathodal forms, LD-4 and LD-5. The decline in activity of the LD-1 and LD-2 isoenzymes results in patterns that are reminiscent of those occurring in embryonic tissues. Tumors of prostate, cervix, breast, brain, stomach, colon, rectum, bronchus, and lymph nodes are among those that show this transformation. In contrast, comparatively benign gliomas show a relative increase in anionic isoenzymes. A relative increase in the proportion of cathodal isoenzymes of LD has also been observed in tissue adjacent to malignant tumors (e.g., the colon), although the cells in these regions are morphologically normal.

The isoenzyme patterns of aldolase, pyruvate kinase, and hexosaminidase have also been shown to undergo a change toward fetus-like patterns in hepatoma.

In 1968, Fishman and his collaborators reported the identification of an ALP in the serum of a patient with metastatic squamous cell carcinoma of the lung that was biochemically and immunologically identical with the ALP of a normal placenta. The newly discovered isoenzyme was termed the *Regan isoenzyme* after the patient in whom it was discovered. The Regan isoenzyme has been detected in tumor tissues and in sera of patients with many types of malignant disease and in some patients with nonmalignant diseases. An incidence of the isoenzyme of 3% to 15% in sera of cancer patients has been estimated, but this varies with the sensitivity of the methods used for its detection. Other variant forms of ALP have since been discovered in tumor tissues. These variants show many similarities to normal placental ALP but may differ in other properties, such as response to certain inhibitors.

Differences in Properties Between Multiple Forms of Enzymes

The structural differences between the multiple forms of an enzyme give rise to greater or lesser differences in physicochemical properties, such as electrophoretic mobility, resistance to inactivation, and solubility, or in catalytic characteristics, such as the ratio of reaction with substrate analogues or response to inhibitors. Methods of isoenzyme analysis have therefore been designed to investigate a wide range of catalytic and structural properties of enzyme molecules.[7] However, it is usually possible to make only limited deductions about the nature of the underlying structural differences between isoenzymes that are responsible for the dissimilar properties. Equally, the changes in catalytic and other properties that may result from specific structural alterations in enzyme molecules can rarely be predicted from current theoretical knowledge of the relationship between structure and function of proteins.

Techniques of molecular biology, such as gene cloning and sequencing, have revolutionized the investigation of the primary structures of isoenzymes. The differences in primary structures between isoenzymes, whether derived from multiple gene loci or different alleles, are now known in a growing number of cases. Furthermore, many questions have been answered about whether multiple enzyme forms represented true (genetically determined) isoenzymes or arose from posttranslational modification.

Isoenzymes caused by the existence of multiple-gene loci usually differ quantitatively in catalytic properties. These differences may be manifested in such characteristics as molecular activity, K_m values for substrate(s), sensitivity to various inhibitors, and relative rates of activity with substrate analogues (when the specificity of the isoenzymes allows the substrate to be varied), underscoring the biological importance of isoenzymatic variation. In contrast, multiple enzyme forms that arise by such posttranslational modifications as aggregation usually have similar catalytic properties.

Multilocus isoenzymes also usually differ in antigenic specificity, although these differences may be less pronounced among isoenzymes that have emerged relatively recently in evolutionary history and are closely related in structure. Immunological cross-reaction is also not uncommon among multilocus isoenzymes. Multiple enzyme forms caused by postsynthetic modification frequently have common antigenic determinants. Isoenzymes derived from allelic genes (allozymes) are often antigenically similar, even to the extent that they may cross-react with antisera to the common isoenzyme even when a mutation has abolished enzyme activity altogether. The capacity for detecting differences between antigenically similar isoenzyme molecules depends on the extent of monoclonal antibody specificity.

Differences in resistance to denaturation (e.g., by heat or concentrated urea solutions) are commonly found between true isoenzymes, whether these are the products of multiple

loci or multiple alleles. Other multiple forms of enzymes often do not differ or differ only slightly in this respect. The most commonly exploited difference between isoenzymes is the difference in net molecular charge that results from the altered amino acid compositions of the molecules; this forms the basis of separation by zone electrophoresis, ion-exchange chromatography, or isoelectric focusing. Separation methods that depend on differences in molecular size, such as gel filtration, do not distinguish between the small differences in size that often exist between true isoenzyme molecules but are important in the detection of multiple forms that involve aggregation or association of enzyme molecules with other proteins.

Enzymes as Catalysts

A *catalyst* is a substance that increases the rate of a particular chemical reaction without being consumed or permanently altered; enzymes are *protein catalysts* of biological origin. Metabolism is a coordinated series of chemical reactions that occur within a living cell to provide energy and accomplish biosynthesis. The process can be regarded as an integrated series of enzymatic reactions and some diseases as a derangement of the normal pattern of metabolism. Apart from these fundamental considerations, it is the remarkable properties of enzymes that make them such sensitive indicators of pathological change.

Efficiency

Because of their remarkable catalytic activity, a given number of enzyme molecules convert an enormous number of substrate molecules to products within a short time. Therefore, the appearance of increased amounts of enzymes in the blood stream is easily detected, although the amount of enzyme protein released from damaged cells is small compared with the total level of nonenzymatic proteins in blood. Thus a particular enzyme is recognized by its characteristic effect on a given chemical reaction despite the presence of a vast excess of other proteins.

Like other catalysts, an enzyme changes only the rate at which equilibrium is established between reactants and products; it does not alter the equilibrium constant of the reaction. In a reaction in which only one set of products is chemically possible, the catalyst cannot effect any change in the nature of the products. But when several different possible pathways exist, the enzyme directs the reaction along only one pathway.

Specificity and the Active Center

With the exception of enzymes such as proteases, nucleases, and amylases, which act on macromolecular substrates, enzyme molecules are considerably larger than the molecules of their substrates. Consideration of the structure of an enzyme's active site and its relationship to the structures of the enzyme's substrate(s) in its ground and transition states is necessary to understand the rate enhancement and specificity of the chemical reactions performed by the enzyme. The active site of an enzyme will vary between enzymes but in general:[2]

1. The active site of an enzyme is relatively small compared with the total volume of the enzyme molecule because its structure may involve less than 5% of the total amino acids in the molecule.
2. The active sites of enzymes are three-dimensional structures that are formed as a result of the overall tertiary structure of the protein. This results from the amino acids and co-factors in the active site of an enzyme being spatially structured in an exact, three-dimensional relationship with respect to one another and the structure of the substrate molecule.
3. Typically, the attraction between the molecules of the enzyme and its substrate molecules is noncovalent binding. Physical forces used in this type of binding include hydrogen bonding, electrostatic and hydrophobic interactions, and van der Waals forces.
4. Active sites of enzymes typically occur in clefts and crevices in the protein. This excludes bulk solvent and reduces the catalytic activity of the enzyme.
5. The specificity of substrate binding is a function of the exact special arrangement of atoms in the enzyme active site that complements the structure of the substrate molecule.

ENZYME KINETICS

The Enzyme-Substrate Complex

Enzymes act through the formation of an enzyme-substrate (*ES*) complex, in which a molecule of substrate is bound to the *active center* of the enzyme molecule. The binding process transforms the substrate molecule to its activated state. The energy required for this transformation is provided by the free energy of binding of *S* to *E*. Therefore activation takes place without the addition of external energy so that the energy barrier to the reaction is lowered and the breakdown to products is accelerated (see Figure 8-3). The ES complex breaks down to give the reaction products (*P*) and free enzyme (*E*):

$$E + S \rightleftharpoons ES \longrightarrow P + E \qquad (1)$$

All reactions catalyzed by enzymes are in theory reversible. However, in practice the reaction is usually found to be more rapid in one direction than in the other, so that an equilibrium is reached in which the product of either the forward or the backward reaction predominates, sometimes so markedly that the reaction is virtually irreversible.

If the product of the reaction in one direction is removed as it is formed (e.g., because it is the substrate of a second enzyme present in the reaction mixture), the equilibrium of the first enzymatic process will be displaced so that the reaction will proceed to completion in that direction. Reaction sequences in which the product of one enzyme-catalyzed reaction becomes the substrate of the next enzyme and so on, often through many stages, are characteristic of biologi-

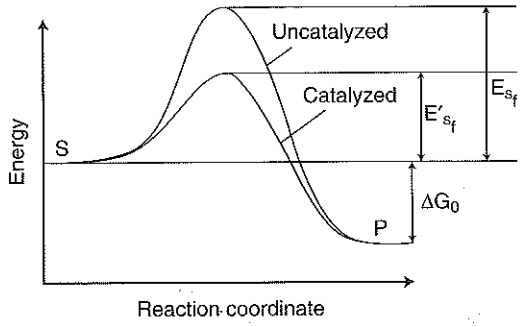

Figure 8-3 Activation energy barrier and reaction course, with and without enzyme catalysis. E_{s_f} is the activation energy for the forward reaction (S → P) in the absence of a catalyst and E'_{s_f} is the activation energy in the presence of a catalyst. ΔG_0 is the change in free energy for the reaction.

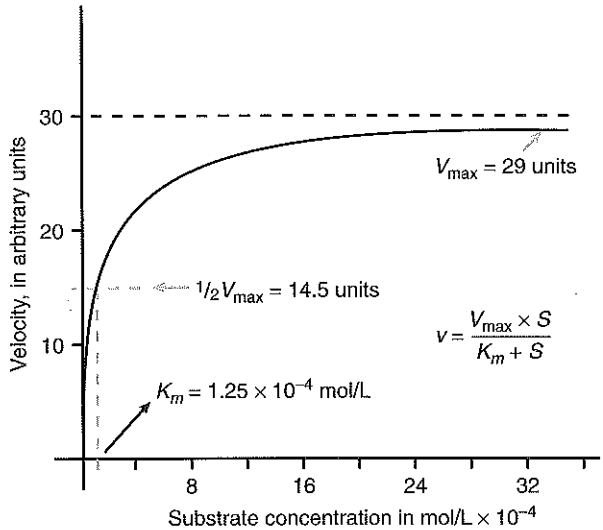

Figure 8-4 Michaelis-Menten curve relating velocity (rate) of an enzyme-catalyzed reaction to substrate concentration. The value of K_m is given by the substrate concentration at which one half of the maximum velocity is obtained.

cal processes. In the lab also, several enzymatic reactions may be linked together to provide a means of measuring the activity of the first enzyme or the concentration of the initial substrate in the chain. For example, the activity of CK is usually measured by a series of linked reactions, and the concentration of glucose is determined by consecutive reactions catalyzed by hexokinase and glucose-6-phosphate dehydrogenase.

When a secondary enzyme-catalyzed reaction, known as an *indicator reaction,* is used to determine the activity of a different enzyme, the primary reaction catalyzed by the enzyme to be determined must be the rate-limiting step. Conditions are chosen to ensure that the rate of reaction catalyzed by the indicator enzyme is directly proportional to the rate of product formation in the first reaction.

Factors Governing the Rate of Enzyme-Catalyzed Reactions

Factors that affect the rate of enzyme-catalyzed reactions include enzyme and substrate concentration, pH, temperature, and the presence of inhibitors, activators, co-enzymes, and prosthetic groups.

Enzyme Concentration

The simplest enzymatically catalyzed reaction for converting substrate S into product P with the intermediate formation of an ES complex, is:

$$E_f + S \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ES \xrightarrow{k_2} E_f + P \qquad (2)$$

where

E_f = free enzyme
k_1 = rate constant for the association of the complex
k_{-1} = rate constant for the dissociation of the complex
ES = enzyme-substrate complex
k_2 = rate constant for breakdown of ES to E_f and P
P = product

Michaelis and Menten assumed that equilibrium is attained rapidly among E, S, and ES with the effect of product formation (ES → P) on the concentration of ES being negligible. In addition, the formation of product is written as an irreversible process because there is no product in the solution under initial conditions. Therefore the overall rate of the reaction under otherwise constant conditions is proportional to the concentration of the ES complex.

Provided that an excess of free substrate molecules is present, addition of more enzyme molecules to the reaction system increases the concentration of the ES complex and thus the overall rate of reaction. This accounts for the observation that the rate of reaction is generally proportional to the concentration of enzyme present in the system and is the basis for the quantitative determination of enzymes by measurement of reaction rates. Reaction conditions are selected to ensure that the observed reaction rate is proportional to enzyme concentration over as wide a range as possible.

Substrate Concentration

In addition to explaining the dependence of reaction rate on enzyme concentration under conditions in which excess substrate is present, the formation of an ES complex also accounts for the hyperbolic relationship between reaction velocity and substrate concentration (Figure 8-4). In this section both single-, two-substrate, and consecutive enzyme reactions will be discussed.

Single-Substrate Reactions

If the enzyme concentration is fixed and the substrate concentration is varied, the rate of reaction is first order with respect to substrate concentration and proportional to substrate concentration at low values of the latter. Under these conditions, only a fraction of the enzyme is associated with substrate, and the rate observed reflects the low concentra-

tion of the ES complex. At high substrate concentrations, variation in substrate concentration has no effect on rate, and the reaction is zero order with respect to substrate concentration. Under these conditions, all the enzyme is bound to the substrate, and a much higher rate of reaction is obtained. Moreover, because all the enzyme is now present in the form of the complex, no further increase in complex concentration and no further increment in reaction rate are possible. The maximum possible velocity for the reaction has been reached. The significance of substrate-rate curves was first emphasized by Michaelis and Menten, and such curves are referred to as *Michaelis-Menten plots.*

Referring again to equation (2), the overall rate of the reaction (v) is determined by the rate at which product is formed:

$$v = \frac{d[P]}{dt} = k_2[ES] \tag{3}$$

The formation of ES will depend on the rate constant k_1 and the availability of enzyme and substrate. If it its assumed the system is in a steady state with the ES complex being formed and broken down at the same rate so that overall $[ES]$ is constant, then the steady state equation is

$$k_1[E][S] = k_{-1}[ES] + k_2[ES] \tag{4}$$

This equation can be rearranged to

$$[ES] = \frac{k_1[E][S]}{k_{-1} + k_2} \tag{5}$$

when these rate constants are combined into a single term, the Michaelis constant (K_m) written as

$$K_m = \frac{k_{-1} + k_2}{k_1} \tag{6}$$

and then substituting this into equation (5) gives

$$[ES] = \frac{[E][S]}{K_m} \tag{7}$$

Because the amount of ES will be a negligible fraction of the total ($[S] >>> [E]$), the concentration of free substrate is equated to the total substrate concentration. By substituting equation (3) into equation (7) and eliminating $[ES]$

$$v = k_2 \times \frac{[E_t] \times [S]}{K_m + [S]} \tag{8}$$

For a given amount of enzyme, the maximum reaction velocity (V_{max}) is reached when all of the enzyme is saturated with substrate (i.e., $[ES] = [Et]$) and therefore, $V_{max} = k_2 \times [Et]$. Substituting this in equation (6) gives

$$v = \frac{V_{max}[S]}{K_m + [S]} \tag{9}$$

A plot of v against $[S]$ gives a section of a rectangular hyperbola (see Figure 8-4), and this is the shape of the curve that is found experimentally for most enzymes. When $[S] = K_m$, manipulation of equation (9) yields $v = \frac{V_{max}}{2}$, thus K_m is the substrate concentration at which the reaction proceeds at one half of its maximum velocity. In practice, it is now customary to restrict K_m to the experimentally determined substrate concentration at which $v = 0.5\ V_{max}$ and to use the symbol K_s to represent the true ES association constant, where this is known.

Although it is quite simple to set up an experiment to determine the variation of v with $[S]$, the exact value of V_{max} is not easily determined from hyperbolic curves. Furthermore, many enzymes deviate from ideal behavior at high substrate concentrations and indeed may be inhibited by excess substrate, so the calculated value of V_{max} cannot be achieved in practice. In the past it was common practice to transform the Michaelis-Menten equation (9) into one of several reciprocal forms (equations [10] and [11]), and either $1/v$ was plotted against $1/[S]$, or $[S]/v$ was plotted against $[S]$.

$$\frac{1}{v} = \left(\frac{K_m}{V_{max}} \times \frac{1}{[S]}\right) + \frac{1}{V_{max}} \tag{10}$$

$$\frac{[S]}{v} = \left(\frac{1}{V_{max}} \times [S]\right) + \frac{K_m}{V_{max}} \tag{11}$$

Equation (10), for example, when plotted, results in a *Lineweaver-Burk* plot that gives a straight line with intercepts at $1/V_{max}$ on the ordinate and $-1/K_m$ on the abscissa. For illustrative purposes, the data for Figure 8-4 are recast in Lineweaver-Burk form in Figure 8-5. Regarding inhibition, the Michaelis-Menten curve and its linearized plots are altered in a way that is described later.

It is now routine practice to determine kinetic constants such as K_m and V_{max} using a software package. There are a large number of such packages available that vary from specialized routines for kinetic simulations or for data fitting to general mathematical, statistical, or graphical packages (http://med.umich.edu/biochem/enzresources/software.ttm). Some of these packages are free (public domain, shareware, or free license) or commercially available. An example of the former is the ENCORA 1.2 freeware package available from R.J.W. Slats and colleagues at the Delft University of Technology (http://www.bt.tudelft.nl/), that was developed for an enzymatic kinetic parameter fitting using progressive curve analysis. DynaFit is an example of a commercially available routine (http://www.biokin.com/dynafit) that performs nonlinear least-squares regression of chemical kinetic, enzyme kinetic, or ligand receptor binding data. The data can be either initial reaction velocities in dependence on the concentration of varied species (e.g., inhibitor concentration vs. velocity), or the reaction progress curves (e.g., time vs. absorbance).

The value of K_m has been used to compare the binding of homologous or related substrates to the same enzyme. Also, if measured against the same substrate under defined conditions, the K_m value can be used to compare the properties

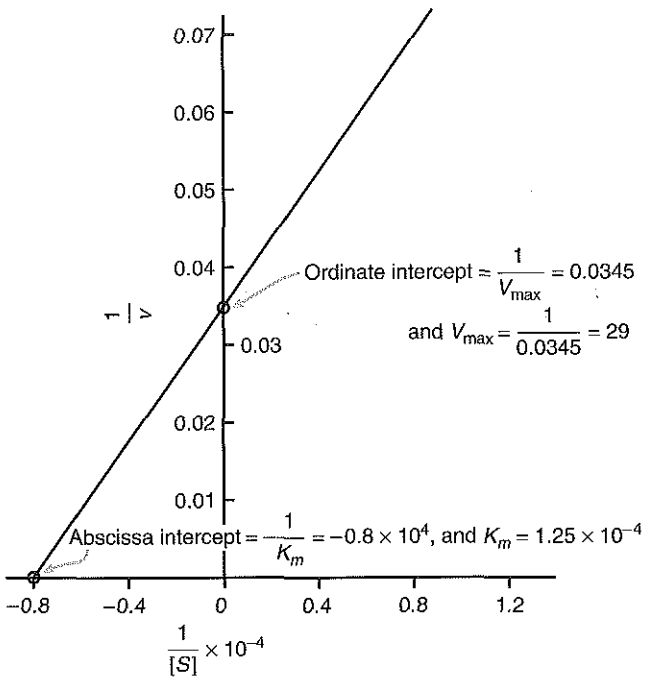

Figure 8-5 Lineweaver-Burk transformation of the curve in Figure 8-4, with $1/v$ plotted on the ordinate (y-axis), and $1/[S]$ on the abscissa (x-axis). The indicated intercepts permit calculation of V_{max} and K_m. The units of v and $[S]$ are those given in Figure 8-4.

of similar enzymes from different sources. Isoenzymes determined by distinct genetic loci typically differ in their K_m, as has been shown (e.g., for the isoenzymes of lactate dehydrogenase.)

When setting up methods of enzyme assay, it is necessary to (1) explore the relationship between reaction velocity and substrate concentration over a wide range, (2) determine K_m, and (3) detect any inhibition at high substrate concentrations. Zero-order kinetics are maintained if the substrate is present in large excess (i.e., concentrations at least 10 and preferably 100 times that of the value of K_m). When $[S] = 10 \times K_m$, v is approximately 91% of the theoretical V_{max}. The K_m values for the majority of enzymes are of the order of 10^{-5} to 10^{-3} mol/L; therefore substrate concentrations are usually chosen to be in the range of 0.001 to 0.10 mol/L. On occasion, the optimal concentrations of substrate cannot be used (e.g., when the substrate has limited solubility or when the concentration of a given substrate inhibits the activity of another enzyme needed in a coupled reaction system).

Two-Substrate Reactions

Most enzymes catalyze reactions with two or more interacting substrates symbolized by the following equation:

$$\underset{S_1}{\text{Substrate 1}} + \underset{S_2}{\text{Substrate 2}} \overset{E}{\rightleftharpoons} \underset{P_1}{\text{Product 1}} + \underset{P_2}{\text{Product 2}} \quad (12)$$

When one of the substrates is water (i.e., when the process is one of hydrolysis), with the reaction taking place in aqueous solution, only a fraction of the total number of water molecules present participates in the reaction. The small change in the concentration of water has no effect on the rate of reaction and these pseudo–one substrate reactions are described by one-substrate kinetics. More generally the concentrations of both substrates may be variable, and both may affect the rate of reaction. Among the bisubstrate reactions important in clinical enzymology are the reactions catalyzed by dehydrogenases, in which the second substrate is a specific coenzyme, such as the oxidized or reduced forms of nicotinamide adenine dinucleotide, (NADH), or nicotinamide adenine dinucleotide phosphate, (NADPH), and the amino-group transfers catalyzed by the aminotransferases.

If a bisubstrate reaction proceeds by way of intermediate ES complexes, so that

$$E + S_1 \rightleftharpoons ES_1 \quad (13)$$

followed by

$$ES_1 + S_2 \rightleftharpoons ES_1S_2 \longrightarrow P_1 + P_2 + E \quad (14)$$

and if S_1 and S_2 combine with separate sites on the enzyme molecule, the rate of reaction is given by

$$v = \frac{V_{max} \times [S_1][S_2]}{[S_1][S_2] + [S_2]K_m^1 + [S_1]K_m^2 + K_s^1 K_m^2} \quad (15)$$

K_m^1 and K_m^2 are the K_m values for the two substrates, and $[S_1]$ and $[S_2]$ are their concentrations. K_s^1 is the equilibrium constant for the reversible reaction between the enzyme and S_1. If the equation is rearranged into the double reciprocal form

$$\frac{1}{v} = \frac{1}{[S_1]}\left(\frac{K_m^1}{V_{max}} + \frac{K_m^2 K_s^1}{[S_2]V_{max}}\right) + \frac{1}{V_{max}}\left(1 + \frac{K_m^2}{[S_2]}\right) \quad (16)$$

a plot of $1/v$ against $1/[S_1]$ gives a straight line, but both the slope of the line and its intercept on the ordinate are affected by $[S_2]$, the concentration of the second substrate (Figure 8-6, *A*). Similarly, a plot of $1/v$ against $1/[S_2]$ is rectilinear but with the slope and intercept dependent on $[S_1]$.

Values of K_m and V_{max} for each substrate are derived from experiments in which the concentration of the first substrate is held constant at saturating levels while the concentration of the second substrate is varied, and vice versa. There is no reason why the K_m values for the two substrates should be the same or even similar (e.g., pyruvate and NADH, the two-substrate pair in the reaction catalyzed by lactate dehydrogenase of beef heart, have K_m values of 2×10^{-5} mol/L and 3×10^{-6} mol/L, respectively).

In some bisubstrate reactions, no ternary complex ES_1S_2 is formed, because the binding of the first substrate is followed by release of the first product before the second substrate is bound and the second product is released. This sequence is described as a *ping-pong bi-bi* type of reaction. It occurs in reactions catalyzed by aminotransferases.

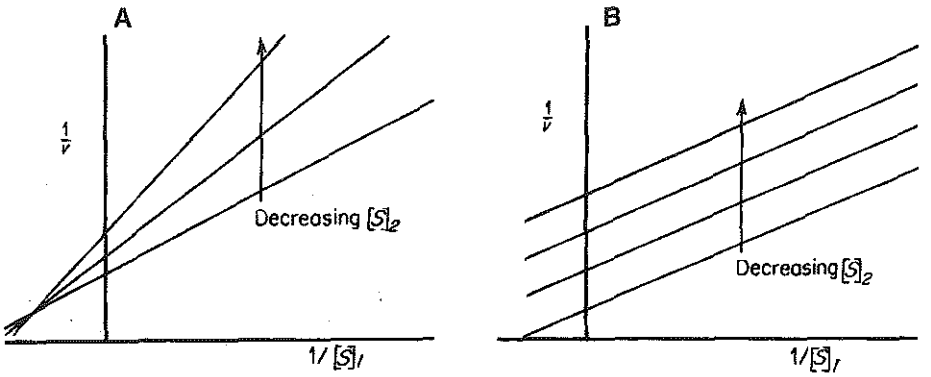

Figure 8-6 Double-reciprocal plots of $1/v$ against $1/[S_1]$ for two-substrate reactions, showing the effect of falling concentration of the second substrate, $[S_2]$. **A,** In a dehydrogenase reaction in which a ternary complex is formed. **B,** In a *ping-pong bi-bi* reaction mechanism (e.g., aminotransferase) in which no ternary complex is formed. *(From Moss DW. Measurement of enzymes. In: Enzymes in cardiology: Diagnosis and research. Hearse DJ, de Leiris J, Eds. New York: John Wiley & Sons Inc, 1979. Reprinted by permission of John Wiley & Sons, Inc.)*

The relationship between reaction velocity and the concentrations of the two substrates in *ping-pong bi-bi* reactions reduces to the form

$$v = \frac{V_{max} \times [S_1][S_2]}{[S_1][S_2] + [S_2]K_m^1 + [S_1]K_m^2} \quad (17)$$

The reciprocals of v and $[S_1]$ are related by the equation

$$\frac{1}{v} = \frac{1}{[S_1]} \times \frac{K_m^1}{V_{max}} + \frac{1}{V_{max}}\left(1 + \frac{K_m^2}{[S_2]}\right) \quad (18)$$

so that a plot of $1/v$ against $1/[S_1]$ is unchanged in slope by variation in $[S_2]$, but the intercept on the ordinate and therefore the value of V_{max} changes as $[S_2]$ is varied (see Figure 8-6, *B*). Similar equations describe the variation of V_{max} with $[S_1]$ when $1/v$ is plotted as a function of $1/[S_2]$.

The selection of reaction conditions for the measurement of enzymatic activity involving two substrates is approached empirically by varying the concentration of the first substrate and keeping the concentration of the second substrate constant until maximum activity is reached. The process is then repeated with the concentration of the first substrate held at the value thus determined, while the concentration of the second substrate is varied.

In practice, the choice of substrate concentrations is limited by such considerations as the solubility of the substrates, the viscosity and high initial absorbance of concentrated solutions, and the relative costs of the reagents. Furthermore, the selection of appropriate substrate concentrations is only one of the factors to be considered in formulating an optimal assay system for the measurement of a specific enzyme activity. Critical choices must also be made with respect to other, frequently interdependent factors that affect reaction rate, such as the concentrations of activators and the nature and pH of the buffer system. The traditional empirical approach to optimization has been replaced by newer techniques of simplex co-optimization and response-surface methodology.[11] As an example, this technique has recently been used to determine optimum conditions for the IFCC-recommended method for amylase.[6]

Consecutive Enzymatic Reactions

As discussed above, an enzymatic reaction is usually found to be more rapid in one direction than the other so that the reaction is virtually irreversible.If the product of the reaction in one direction is removed as it is formed (i.e., because it is the substrate of a second enzyme present in the reaction mixture), the equilibrium of the first enzymatic process is displaced so that the reaction may continue to completion in that direction. Reaction sequences in which the product of one enzyme-catalyzed reaction becomes the substrate of another enzyme, often through many stages, are characteristic of metabolic processes. Analytically, several enzymatic reactions also may be linked together to provide a means of measuring the activity of the first enzyme or the concentration of the initial substrate in the chain. For example, the activity of creatine kinase is usually measured by a series of linked reactions, and glucose can be determined by consecutive reactions catalyzed by hexokinase and glucose-6-phosphate dehydrogenase.

When a linked enzyme assay, known as an *indicator reaction*, is used to determine the activity of a different enzyme, it is essential that the primary reaction be the rate-limiting step. For example, in the determination of aspartate aminotransferase activity, the indicator reaction is the reduction of the oxaloacetate formed in the aminotransferase reaction to malate by malate dehydrogenase and NADH. The activity of the indicator enzyme must be sufficient to ensure the virtually instantaneous removal of the product of the first reaction, to prevent significant reversal of the first reaction. The measured enzyme is typically acting under conditions of saturation with respect to its substrate; however, the concentration of the substrate of the indicator enzyme (i.e., the

product of the first reaction) remains in the region of the Michaelis-Menten curve in which v is directly proportional to $[S]$. Therefore the rate of reaction catalyzed by the indicator enzyme is directly proportional to the rate of product formation in the first reaction.

During a lag period that occurs after the start of the first reaction, the concentration of its product reaches a steady state. Because the rate of the second reaction depends on the activity of the indicator enzyme and on the concentration of its substrate (the product of the primary reaction), the duration of the lag period is reduced by increasing the concentration of the indicator enzyme, thus lowering the steady-state concentration of the product of the primary reaction.

The rate of the indicator reaction, v_i, is related to substrate concentration and therefore to the product concentration [P] by the Michaelis-Menten equation

$$v_i = \frac{V^i_{max} \times [P]}{[P] + K^i_m} \tag{19}$$

in which V^i_{max} and K^i_m are the maximum velocity and K_m of the indicator enzyme, respectively. For the rate of the indicator reaction not to be the rate limiting factor, vi must at least equal the limiting velocity of the primary reaction, vt, which the assay system is expected to measure. Therefore the minimum activity of indicator enzyme needed is given by

$$v_t = \frac{V^i_{max} \times [P]}{[P] + K^i_m} \tag{20}$$

or rearranged

$$V^i_{max} = v_t\left(1 + \frac{K^i_m}{[P]}\right) \tag{21}$$

The ratio of activities of the indicator and primary enzymes varies from one assay method to another, depending on (1) the range of activity measured, (2) the K_m of the indicator enzyme, and (3) the lag period that is considered acceptable. Nevertheless the catalytic concentration of the indicator enzyme in the reaction mixture must always be much greater than that of the enzyme being determined.

Effect of pH

The rate of enzyme-catalyzed reactions typically shows a marked dependence on pH (Figure 8-7). Many of the enzymes in blood plasma show maximum activity in vitro in the pH range from 7 to 8. However, activity has been observed at pH values as low as 1.5 (pepsin) and as high as 10.5 (ALP). The optimal pH for a given forward reaction may be different from the optimal pH found for the corresponding reverse reaction. The form of the pH-dependence curve is a result of a number of separate effects including the ionization of the substrate and the extent of dissociation of certain key amino acid side chains in the protein molecule, both at the active center and elsewhere in the molecule. Both pH and ionic environment will also have an effect on the three-dimensional conformation of the protein and

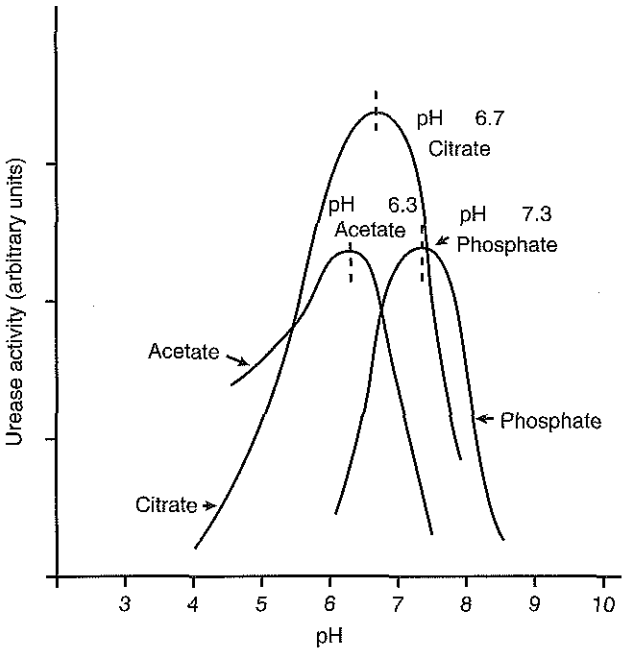

Figure 8-7 The pH activity curves for urease show effect of buffer species on pH optimum. *(Modified from Howell SF, Sumner JB. J Biol Chem 1934;104:619.)*

therefore on enzyme activity to such an extent that enzymes may be irreversibly denatured at extreme values of pH.

The pronounced effects of pH on enzyme reactions emphasize the need to control this variable by means of adequate buffer solutions. Enzyme assays should be carried out at the pH of optimal activity, because the pH-activity curve has its minimum slope near this pH, and a small variation in pH will cause a minimal change in enzyme activity. The buffer system must be capable of counteracting the effect of adding the specimen (e.g., serum itself is a powerful buffer) to the assay system, and the effects of acids or bases formed during the reaction (e.g., formation of fatty acids by the action of lipase). Because buffers have their maximum buffering capacity close to their pK_a values, whenever possible a buffer system should be chosen with a pK_a value within 1 pH unit of the desired pH of the assay (see Chapter 1). Interaction between buffer ions and other components of the assay system (e.g., activating metal ions) may eliminate certain buffers from consideration.

Temperature

The rate of an enzymatic reaction is proportional to its reaction temperature. For most enzymatic reactions, values of Q_{10} (the relative reaction rates at two temperatures differing by 10 °C) vary from 1.7 to 2.5. However, an increase in the rate of the catalyzed reaction is not the only effect of increasing temperature on an enzymatic reaction. In theory, the initial rate of reaction measured instantaneously will increase with a rising temperature. In practice, however, a

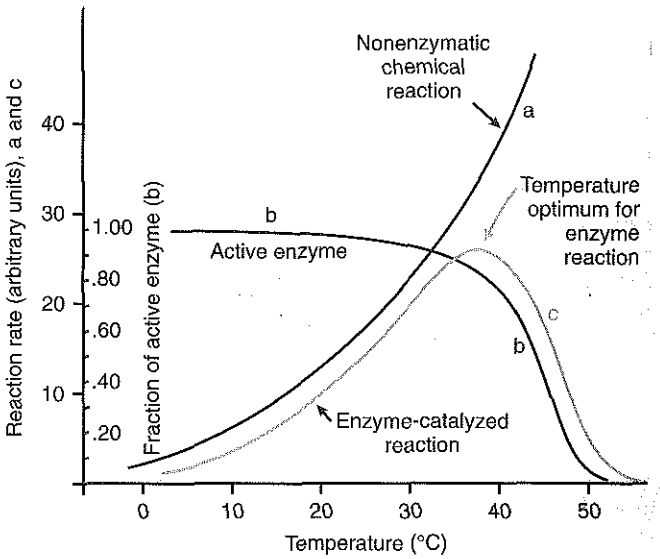

Figure 8-8 Schematic diagram showing effect of temperature on the rate of nonenzyme-catalyzed and enzyme-catalyzed reactions.

finite time is needed to allow the components of the reaction mixture, including the enzyme solution, to reach temperature equilibrium and to permit the formation of a measurable amount of the product. During this period the enzyme is undergoing thermal inactivation and denaturation, a process that has a very large temperature coefficient for most enzymes and thus becomes virtually instantaneous at temperatures of 60 °C to 70 °C. The counteracting effects of the increased rate of the catalyzed reaction and more rapid enzyme inactivation as the temperature increases account for the existence of an apparent *optimal temperature* for enzyme activity (Figure 8-8).

As stated earlier, at some critical temperature, an enzyme will undergo thermal inactivation influenced by a number of factors. These include the presence of substrate and its concentration, the pH, and the nature and ionic strength of the buffer. The presence of other proteins, as in serum samples, may help to stabilize enzymes. Storage of serum samples at low temperatures is necessary to minimize loss of enzyme activity while awaiting analysis, although repeated freezing and thawing should be avoided. However, individual enzymes vary in their stability characteristics, and appropriate storage conditions vary correspondingly. Amylase, for example, is stable at room temperature (22 °C to 25 °C) for 24 hours, whereas acid phosphatase is exceedingly unstable, even when refrigerated, unless kept at a pH below 6.0. ALP exhibits an unusual property: the tendency for the activity of frozen, partially purified preparations of the enzyme to increase after thawing over a period of 24 hours or longer. This effect is shared by reconstituted, lyophilized preparations of the enzyme and affects their use for quality control purposes. A few enzymes are inactivated at refrigerator temperatures; a clinically important example is the liver-type isoenzyme of lactate dehydrogenase, LD-5, which appears to be less stable at lower temperatures. As a result, sera for lactate dehydrogenase determinations should be kept at room temperature and not refrigerated.

Historically, the choice of temperature for the assay of enzymes of clinical importance has been the subject of extensive debate. Currently, the choice of reaction temperature has become a nonissue because most if not all analytical systems operate at 37 °C. In addition, reference methods for several clinically relevant enzymes have now been qualified at 37 °C.[12-17] In practice, accurate temperature control to within ±0.1 °C during the enzymatic reaction is essential. An accurate temperature standard that readily is transferred from one laboratory to another is provided by the gallium melting-point cell.[1] Pure gallium melts at 29.77 °C.

Inhibitors and Activators

The rates of enzymatic reactions are often affected by substances other than the enzyme or substrate. These modifiers may be inhibitors because their presence reduces the reaction rate or activators as they increase the rate of reaction. Activators and inhibitors are usually small molecules (compared with the enzyme itself) or even ions. They vary in specificity from modifiers that exert similar effects on a wide range of different enzymatic reactions at one extreme, to substances that affect only a single reaction. Reagents, such as strong acids or multivalent anions and cations that denature or precipitate proteins, destroy enzyme activity and thus may be regarded as extreme examples of nonspecific enzyme inhibitors. These effects are not usually included in discussions of enzyme inhibition, although they have obvious practical implications in the treatment and storage of specimens in which enzyme activity is to be measured. The activity of some enzymes depends on the presence of particular chemical groups, such as reduced sulfhydryl (–SH) groups, in the active center. Reagents that alter these groups (e.g., oxidants of SH groups) therefore act as general inhibitors of such enzymes.

Some phenomena of enzyme activation or inhibition are caused by interaction between the modifier and a nonenzymatic component of the reaction system, such as the substrate (e.g., Mg^{2+} combining with ATP to form MgATP, the required substrate for the creatine kinase reaction). In most cases, however, the modifier combines with the enzyme itself in a manner analogous to the combination of enzyme and substrate.

Inhibition of Enzyme Activity

Inhibitors are classified into reversible and irreversible types. *Reversible inhibition* implies that the activity of the enzyme is fully restored when the inhibitor is removed from the system in which the enzyme acts by some physical separative process, such as dialysis, gel filtration, or chromatography. An *irreversible inhibitor* combines covalently with the enzyme so that physical methods are ineffective in separating the two. For example, organophosphorus compounds are

extremely potent irreversible inhibitors of esterases, including acetylcholinesterase. The enzyme breaks one of the bonds in the inhibitor, but part of the molecule is left bound to the active center of the enzyme, preventing further activity. In some cases, enzymes that have combined with irreversible inhibitors can be reactivated by a chemical reaction that removes the blocking group (e.g., the phosphoryl enzymes formed with organophosphorus compounds can sometimes be reactivated by treatment with oximes or hydroxamic acids).

Reversible Inhibition. Reversible inhibition is characterized by the existence of equilibrium between enzyme, *E*, and inhibitor, *I*:

$$E + I \rightleftharpoons EI \qquad (22)$$

The equilibrium constant of the reaction, *Ki* (the *inhibitor constant*), is a measure of the affinity of the inhibitor for the enzyme, just as K_m generally reflects the affinity of the enzyme for its substrate.

A *competitive* inhibitor is usually a structural analogue of the substrate that can combine with the free enzyme in such a way that it competes with the normal substrate for binding at the active site. The actual rate of the reaction is strictly dependent on the relative concentrations of substrate and inhibitor. Two equilibriums are therefore possible:

$$E + S \rightleftharpoons ES \longrightarrow E + \text{Products}$$

and

$$E + I \rightleftharpoons EI$$

The equation that relates the observed reaction velocity to the concentrations of substrate, [*S*], and inhibitor, [*I*], is:

$$v = \frac{V_{max}[S]}{[S] + K_m\left(1 + \frac{[I]}{K_i}\right)} \qquad (23)$$

This is the Michaelis-Menten equation, but with K_m modified by a term including the inhibitor concentration and inhibitor constant. V_{max} is unaltered. Therefore, curves of *v* against [*S*] in the presence and absence of inhibitor reach the same limiting value at high substrate concentrations, but when the inhibitor is present, K_m is apparently greater. Plots of $1/v$ against $1/[S]$ with and without inhibitor cut the ordinate at the same point but have different slopes and intercepts on the abscissa (Figure 8-9).

Competitive inhibition is responsible for the inhibition of some enzymes by excess substrate because of competition between substrate molecules for a single binding site. In two-substrate reactions, high concentrations of the second substrate may compete with the binding of the first substrate. For example, aspartate aminotransferase is inhibited by excess concentrations of the substrate 2-oxoglutarate, and this inhibition is competitive with respect to L-aspartate. Therefore, to maintain a given velocity at high 2-oxoglutarate concentrations, the concentration of L-aspartate has to be increased above the value needed at lower concentrations of 2-oxoglutarate.

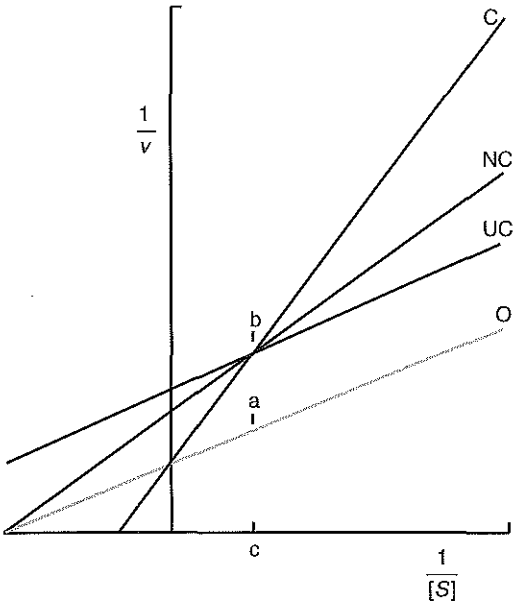

Figure 8-9 Effects of different types of inhibitors on the double-reciprocal plot of $1/v$ against $1/[S]$. Each of the inhibitors has been assumed to reduce the activity of the enzyme by the same amount, represented by the change in $1/v$ from *a* to *b* at a substrate concentration of *c*. *Line O* is the plot for enzyme without inhibitor, *C* with a competitive inhibitor, *NC* with a noncompetitive inhibitor, and *UC* with an uncompetitive inhibitor. *(From Moss DW. Measurement of enzymes. In: Hearse DJ, de Leiris J, Eds. Enzymes in cardiology: Diagnosis and research. New York: John Wiley & Sons Inc, 1979. Reprinted by permission of John Wiley & Sons, Inc.)*

Competitive inhibition also contributes to the reduction of the rate of an enzymatic reaction with time. For example, a rate reduction can occur because increasing concentrations of reaction products tend to drive the reaction backward, if it is freely reversible. A product may itself be an inhibitor of the forward reaction, so even if the reaction is not readily reversible, it proceeds against a rising concentration of inhibitor. A familiar example of "product inhibition" is the release of the competitive inhibitor, inorganic phosphate, by the action of ALP on its substrates. In this case, both organic phosphates and inorganic phosphates bind to the active center of the enzyme with similar affinities (i.e., K_m and K_i are of the same order of magnitude).

Product inhibition is a cause of nonlinearity of reaction progress curves during fixed-time methods of enzyme assay. For example, oxaloacetate produced by the action of aspartate aminotransferase inhibits the enzyme, particularly the mitochondrial isoenzyme. The inhibitory product may be removed as it is formed by a coupled enzymatic reaction: malate dehydrogenase converts the oxaloacetate to malate and at the same time oxidizes NADH to NAD^+.

Competitive inhibition by metal ions can arise when two metal ions compete for the same binding site on the enzyme.

Sodium and lithium are potent inhibitors of pyruvate kinase, for which potassium is an obligatory activator.

A *noncompetitive* inhibitor is usually structurally different from the substrate. It is assumed to bind at a site on the enzyme molecule that is different from the substrate-binding site; thus, there is no competition between inhibitor and substrate, and a ternary enzyme-inhibitor-substrate (ESI) complex forms. Attachment of the inhibitor to the enzyme does not alter the affinity of the enzyme for its substrate (i.e., K_m is unaltered) but the ESI complex does not break down to give products. Since the substrate does not compete with the inhibitor for binding sites on the enzyme molecule, increasing the substrate concentration does not overcome the effect of a noncompetitive inhibitor. Thus V_{max} is reduced in the presence of such an inhibitor, whereas K_m is not altered, as the Lineweaver-Burk plot shows (see Figure 8-9).

In a rather unusual type of reversible inhibition, *uncompetitive* inhibition, parallel lines are obtained when plots of $1/v$ against $1/[S]$ with and without the inhibitor are compared (see Figure 8-9); that is, both K_m and V_{max} are decreased. Uncompetitive inhibition is due to a combination of the inhibitor with the ES complex. It is more common in two-substrate reactions, in which a ternary ESI complex forms after the first substrate has combined with the enzyme.

Irreversible Inhibition. Irreversible inhibitors render the enzyme molecule inactive by covalently and permanently modifying a functional group required for catalysis. An irreversible inhibitor is not in equilibrium with the enzyme. Its effect is progressive with time, becoming complete if the amount of inhibitor present exceeds the total amount of enzyme. The rate of the reaction between enzyme and inhibitor is expressed as the fraction of the enzyme activity that is inhibited in a fixed time by a given concentration of inhibitor. The velocity constant of the reaction of the inhibitor with the enzyme is a measure of the effectiveness of the inhibitor.

When the inhibitor is added to the enzyme in the presence of its substrate, the reaction between the enzyme and inhibitor may be delayed because some of the enzyme molecules are combined with the substrate and are therefore protected from reacting with the inhibitor. However, as the substrate molecules react chemically, the active centers become available and inhibition will eventually become complete even though an excess of substrate may initially have been present. Furthermore, addition of more substrate is ineffective in reversing the inhibition in contrast to its effect on reversible competitive inhibition, which is discussed later.

Irreversible inhibitors have been useful in mapping active sites by covalently modifying different types of functional groups in the enzyme molecule to establish whether such groups are necessary for catalytic activity.

A physiologically important category of irreversible enzyme inhibition is produced by the *antienzymes,* exemplified by various trypsin inhibitors. These are proteins that bind to trypsin irreversibly, nullifying its proteolytic activity. One such inhibitor is present in the α_1-globulin fraction of serum proteins; others are found in soybeans and lima beans. Similar proteolysis inhibitors present in plasma prevent the accumulation of excess thrombin and other coagulation enzymes, thus keeping the coagulation process under control.

Inhibition by Antibodies. The combination of enzyme molecules with specific antibodies often has no effect on catalytic activity, which is retained by the enzyme-antibody complex. However, in some cases, reaction of the enzyme and antibody reduces or even abolishes enzymatic activity. The most probable explanation for this type of inhibition is that the antibody molecule restricts access of the substrate molecules to the active center by steric hindrance or, in extreme cases, completely masks the substrate-binding site. However, it appears that some examples of enzyme inhibition by combination with antibodies are caused by a conformational change induced in the enzyme molecule.

Inhibition of the activity of an enzyme molecule labeled with a hapten (e.g., morphine) as a result of combination with a specific antibody is the basis of homogeneous enzyme immunoassay (EMIT, Syva Corp., Palo Alto, Calif.). See Chapter 9 for further details.

Enzyme Activation

Activators are considered to increase the rates of enzyme-catalyzed reactions by promoting formation of the most active state either of the enzyme itself or of other reactants, such as the substrate. This generalization covers a wide variety of mechanisms of activation.

Many enzymes contain metal ions as an integral part of their structures (e.g., zinc in ALP and carboxypeptidase A). The function of the metal may be to stabilize tertiary and quaternary protein structures. Removal of divalent metal ions by treatment with an appropriate concentration of EDTA solution is accompanied by conformational changes with inactivation of the enzyme. The enzyme can often be reactivated by dialysis against a solution of the appropriate metal ion or simply by adding the ion to the reaction mixture. Reactivation may take some time, because rearrangement of the polypeptide chains into the active conformation is not instantaneous.

When the activator ion is an essential part of the functional enzyme molecule, whether as a purely structural element or with an additional catalytic role, it is usually incorporated quite firmly into the enzyme molecule. Therefore it is not usually necessary to add the activator to reaction mixtures, and excess of the ion may even have an inhibitory effect. However, in some cases the activating ion is attached only weakly or transiently to the enzyme (or its substrate) during catalysis. Enzyme samples may therefore be deficient in the ion so that addition of the ion increases the reaction rate or indeed may be essential for the reaction to take place. For example, all phosphate transfer enzymes (kinases), such as creatine kinase, require the essential pres-

ence of Mg^{2+} ions. Other common activating cations are Mn^{2+}, Fe^{2+}, Ca^{2+}, Zn^{2+}, and K^+. More rarely, anions may act as activators. Amylase functions at its maximal rate only if Cl^- or other monovalent anions, such as Br^- or NO_3^-, are present. Addition of 5 mmol/L of chloride increases amylase activity almost threefold, at the same time shifting the pH optimum from 6.5 to 7.0. The chloride ion may combine with a positively charged group in the enzyme, changing the ionization constant of a group important in catalysis. However, other anions—such as bromide—are less effective activators of amylase, so some degree of specificity is involved in the process of activation. Some enzymes require the obligate presence of two activating ions. K^+ and Mg^{2+} are essential for the activity of pyruvate kinase, and both Mg^{2+} and Zn^{2+} are required for ALP activity.

The velocity of the reaction depends on the concentration of a reversible activator in a fashion similar to its dependence on substrate concentration, and an activator constant, K_a, analogous to K_m, can be determined from data relating enzyme activity to increasing activator concentration in the presence of excess substrate. The simplest interpretation of K_a is that it is the dissociation constant of the equilibrium between E and the activator, A. However, this is true only when the combination of enzyme and activator is independent of the reaction between E and S, and the same value for K_a is obtained at all concentrations of the substrate. If the free enzyme and the enzyme-substrate complex have different affinities for the activator, the value for K_a varies with $[S]$.

Apparent activation of an enzyme may be observed whenever a substance that can counteract the presence of some inhibiting agent is added.

Coenzymes and Prosthetic Groups

Coenzymes are usually more complex molecules than activators, although smaller molecules than the enzyme proteins themselves. Some compounds, such as the dinucleotides NAD and NADP, are classified as coenzymes and are specific substrates in two-substrate reactions. Their effect on the rate of reaction follows the Michaelis-Menten pattern of dependence on substrate concentration. The structures of these two coenzymes are identical except for the presence of an additional phosphate group in NADP; nevertheless, individual dehydrogenases, for which these coenzymes are substrates, are predominantly or even absolutely specific for one or the other form.

Coenzymes such as NAD and NADP are bound only momentarily to the enzyme during the course of reaction, as is the case for substrates in general. Therefore no reaction takes place unless the appropriate coenzyme is present in solution (e.g., by adding it to the reaction mixture in the assay of dehydrogenase activity). In contrast to these entirely soluble coenzymes, some coenzymes are more or less permanently bound to the enzyme molecules, where they form part of the active center and undergo cycles of chemical change during the reaction.

The active *holoenzyme* results from the combination of the inactive *apoenzyme* with the *prosthetic group*, as such a bound coenzyme is called. An example of a prosthetic group is pyridoxal phosphate (P-5′-P), a component of AST and ALT. The P-5′-P prosthetic group undergoes a cycle of conversion of the pyridoxal moiety to pyridoxamine and back again during the transfer of an amino group from an amino acid to an oxo-acid. Prosthetic groups, such as activators with a structural role, do not usually have to be added to elicit full catalytic activity of the enzyme unless previous treatment has caused the prosthetic group to be lost from some enzyme molecules. However, both normal and pathological serum samples contain appreciable amounts of apo-aminotransferases, which is converted to the active holoenzymes by a suitable period of incubation with P-5′-P.

A study of the formulas of coenzyme and prosthetic groups shows that many contain structures derived from the vitamins (see Chapter 30). Thus, the nicotinamide portion of NAD and NADP derives from the vitamin niacin, whereas the P-5′-P prosthetic group of the aminotransferases is a derivative of pyridoxine, vitamin B_6. Other derivatives of the B-group vitamins participate in enzymatic reactions.

ANALYTICAL ENZYMOLOGY

Analytically the clinical laboratorian is concerned with measuring the activity or mass in serum or plasma of enzymes that are predominantly intracellular and that are normally present in the serum in low levels only. By measuring changes in the levels of these enzymes in disease, it is possible to infer the location and nature of pathological changes in the tissues of the body.

Measurement of Reaction Rates

The rate of an enzyme-catalyzed reaction is directly proportional to the amount of active enzyme present in the system. Consequently, the determination of the rate of reaction under defined and controlled conditions provides a very sensitive and specific method for the measurement of enzymes in samples such as serum.

Determination of reaction rate involves the kinetic measurement of the amount of change produced in a defined time interval. Both *fixed-time* and *continuous-monitoring* methods are used to measure reaction rates. In the fixed-time method, the amount of change produced by the enzyme is measured after stopping the reaction at the end of a fixed-time interval. In the continuous-monitoring method, the progress of the reaction is monitored continuously. These two methods have different advantages and limitations. To appreciate these, it is necessary to consider the way in which the rate of an enzymatic reaction varies with time.

The progress of conversion of the substrate into products in the presence of an enzyme is monitored by measuring the decreasing concentration of the substrate or the increasing concentration of the products. Measurement of product for-

mation is preferable, as determination of the increase in concentration of a substance above an initially zero or low level is analytically more reliable than measurement of a decline from an initially high level.

At the moment when the enzyme and substrate are mixed, the rate of the reaction is zero. The rate then typically rises rapidly to a maximum value, which remains constant for a period of time (Figure 8-10). During the period of constant reaction rate, the rate depends only on enzyme concentration and is completely independent of substrate concentration. The reaction is said to follow zero-order kinetics, because its rate is proportional to the zero power of the substrate concentration. Ultimately, however, as more substrate is consumed, the reaction rate declines and enters a phase of first-order dependence on substrate concentration. Other factors that contribute to the decline in reaction rate include accumulation of products that may be inhibitory, the growing importance of the reverse reaction, and even enzyme denaturation. Although it is possible to compare the rates of reaction produced by different amounts of an enzyme under first-order conditions, it is obviously easier to standardize such comparisons when the enzyme concentration is the only variable that influences the reaction rate. Therefore, enzyme assays are usually made under conditions that are initially saturating with respect to substrate concentration. The rate of reaction during the zero-order phase is determined by measuring the product formed during a fixed period of incubation where the rate remains constant. This is illustrated in Figure 8-11. Measurement of reaction rates at any portion of curve A gives results that are identical to the true "initial rate." However, curve B deviates from linearity over its entire course, and rates fall off with time. From curve C, correct results are obtained only if the rate is measured along segment II. Incorrect results are

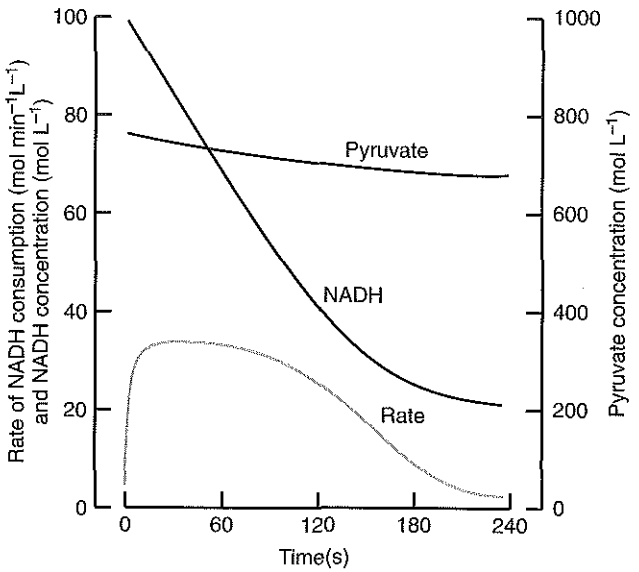

Figure 8-10 Changes in substrate concentrations and rate of reaction during an assay of lactate dehydrogenase activity at 37 °C in phosphate buffer, with pyruvate and NADH as substrates. The reaction is followed by observing the fall in absorbance at 340 nm as NADH is oxidized to NAD^+. The rate of reaction rises rapidly to a maximum value, from which it declines only slightly until about half the NADH has been used up. During this phase of the reaction, the rate is essentially zero order with respect to substrate concentration. At the point at which the rate falls below about 90% of its maximum value, NADH concentration is approximately $10 \times K_m$. The K_m for NADH is of the order of 5×10^{-6} mol/L, whereas for pyruvate it is 9×10^{-5} mol/L. Thus an initial pyruvate concentration approximately 10 times that of NADH is used. (Concentrations are per liter of reaction mixture.) *(From Moss DW. Measurement of enzymes. In: Hearse DJ, de Leiris J, Eds. Enzymes in cardiology: Diagnosis and research. New York: John Wiley & Sons Inc, 1979. Reprinted by permission of John Wiley & Sons, Inc.)*

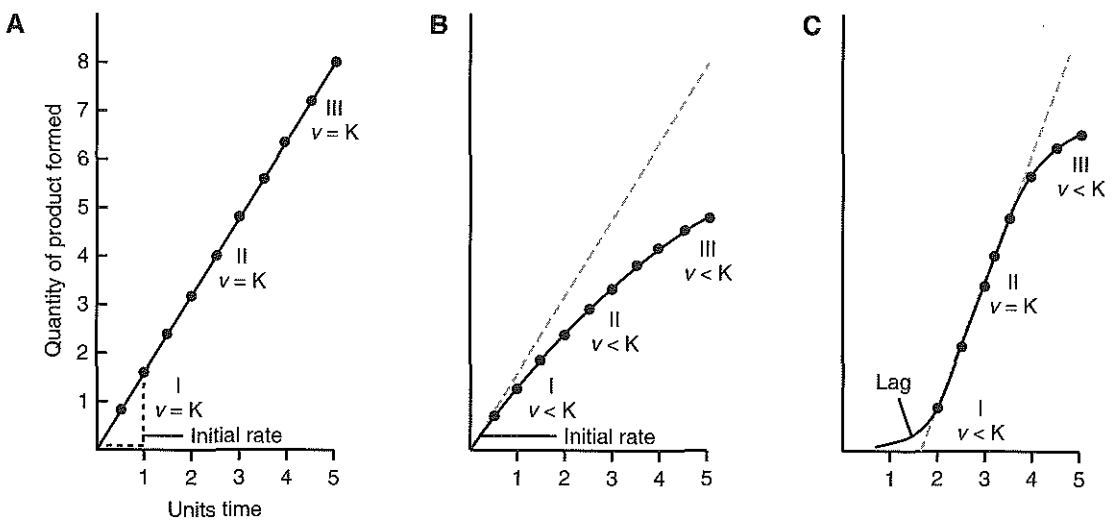

Figure 8-11 Forms of graphs showing change in enzyme reaction rate as a function of time. In **A,** the rate is constant during the entire run, and rates calculated as I, II, and III will be identical to the initial rate. In **B,** the rate falls off continuously; rates calculated at I, II, and III will be different and less than the true initial rate. In **C,** a measurement at II will be representative of the maximum rate, but at I (lag period) and III (substrate depletion), it will be less than at II.

obtained if the rate is measured during the lag phase (I) or during phase III.

Careful selection of reaction conditions, such as the concentrations of substrates and cofactors, improves the reaction progress curves, eliminating lag phases and prolonging the period of linearity, so that fixed-time methods of analysis become feasible. Improvements in optical techniques, leading to more reliable and sensitive measurement of product formation, have also allowed the duration of incubation to be shortened compared with older assays. This has resulted in a corresponding increase in the interval over which enzyme activity is measured. Nevertheless, an upper limit of activity exists in all fixed-time methods, above which progress curves will no longer be linear. In that case the amount of change measured over the fixed-time interval no longer represents true zero-order rate conditions.

The existence of an upper limit of enzyme activity implies that samples with activities above this limit must receive special attention. The upper limit of activity acceptable in the unmodified method must be chosen so that samples with activities below it are presumed with a high degree of certainty to give linear progress curves; on the other hand, if the limit is set too low, many samples will be reanalyzed unnecessarily. Samples that are above the limit should ideally be reassayed by shortening the incubation period until a constant reaction rate is obtained. However, this is difficult or impossible in some automated methods, in which the duration of incubation is fixed by the configuration of the apparatus. It then becomes necessary to dilute the specimen; however, dilution may not always result in a proportionate change in activity.

The initial rate of reaction theoretically increases without limit as enzyme concentration increases, as long as no other factor, such as substrate concentration, becomes limiting. In practice, the reaction rate becomes so rapid at high enzyme activities that it is impossible to measure the initial rate of reaction, even with continuous-monitoring methods. Therefore, an upper limit of activity that is accepted without modification of the assay procedure exists even in continuous-monitoring methods, but this limit is usually much higher than that applicable in corresponding fixed-time methods. Fewer samples therefore require special treatment. Furthermore, continuous monitoring allows identification of the appropriate zero-order portion of the progress curve for each sample and identification of samples that require special treatment. Continuous-monitoring methods therefore possess a decisive advantage in enzyme assay and should be used whenever possible. Enzyme activity can also be measured by noting the time required to consume all of a fixed amount of substrate, but methods of this type have largely been discontinued.

Units for Expressing Enzyme Activity

When enzymes are measured by their catalytic activities, the results of such determinations are expressed in terms of the concentration of the number of activity units present in a convenient volume or mass of specimen. The unit of activity is the measure of the rate at which the reaction proceeds (e.g., the quantity of substrate consumed or product formed in a chosen unit of time). In clinical enzymology, the activity of an enzyme is generally reported in terms of some convenient unit of volume, such as activity per 100 mL or per liter of serum or per 1.0 mL of packed erythrocytes. Because the rate of the reaction depends on experimental parameters, such as pH, type of buffer, temperature, nature of substrate, ionic strength, concentration of activators, and other variables, these parameters must be specified in the definition of the unit.

To standardize how enzyme activities are expressed, the Enzyme Commission of the IUB proposed that the unit of enzyme activity be defined as the quantity of enzyme that catalyzes the reaction of 1 μmol of substrate per minute and that this unit be termed the *international unit* (U). Catalytic concentration is to be expressed in terms of U/L or kU/L, whichever gives the more convenient numerical value. In this chapter, the symbol U is used to denote the international unit. In those instances in which there is some uncertainty about the exact nature of the substrate or when there is difficulty in calculating the number of micromoles reacting (as with macromolecules such as starch, protein, and complex lipids), the unit is to be expressed in terms of the chemical group or residue measured in following the reaction (e.g., glucose units, or amino acid units formed).

The international unit itself may eventually be replaced by the SI unit termed the *katal*, the SI derived unit for catalytic activity (see Chapter 1). It is defined as moles per second. The name katal had been used for this unit for decades, but did not become an official SI derived unit until 1999 with Resolution 12 of the 21st CGPM, on the recommendation of the International Federation of Clinical Chemistry and Laboratory Medicine. Both the International Union of Pure and Applied Chemistry and the IUB now recommend that enzyme activity be expressed in moles per second and that the enzyme concentration be expressed in terms of katals per liter (kat/L).[3] Thus, $1\,U = 10^{-6}$ mol/60 s = 16.7×10^{-9} mol/s, or 1.0 nkat/L = 0.06 U/L. The formal adoption of the katal is hoped to discourage the use of a non-SI unit called "unit," symbol "U," defined as micromoles per minute. "Units" are more commonly used than the katal in practice at present, but their definition lacks coherence with the SI system.

Measurement of Substrates

The amount of substrate transformed into products during an enzyme-catalyzed reaction can be measured with any appropriate analytical method, such as spectrophotometry, fluorometry, or chemiluminescence. For example, if an enzyme reaction is accompanied by a change in the absorbance characteristics of some component of the assay system, in either the visible or ultraviolet spectrum, it can be photometrically observed while it is proceeding. "Self-indicating" reactions of this type are particularly valuable as

they allow continuous monitoring. Important examples of self-indicating reactions are the determination of dehydrogenase activity by monitoring the change in absorbance at 339 (340) nm of the coenzymes NADH or NADPH during oxidation or reduction and the measurement of ALP activity by the generation of the yellow *p*-nitrophenolate ion from the substrate *p*-nitrophenyl phosphate in alkaline solution. These assays are so versatile that coupled reactions are frequently used to provide an observable optical change accompanying a primary reaction in which such a change is not present.

The introduction of prism or diffraction-grating spectrophotometers capable of isolating a narrow beam of monochromatic light in the ultraviolet or visible spectrum and with stable and sensitive photomultipliers as detectors greatly improved the reproducibility of photometric measurements. Consequently, it has become customary to make use of the known molar absorptivity of well-defined reaction products (such as NADH) when calculating changes in their concentrations based on measurements made with spectrophotometers. However, the absorbance and wavelength accuracy of the spectrophotometer should be checked regularly. (See Chapter 3 for details of validating the performance of a spectrophotometer.)

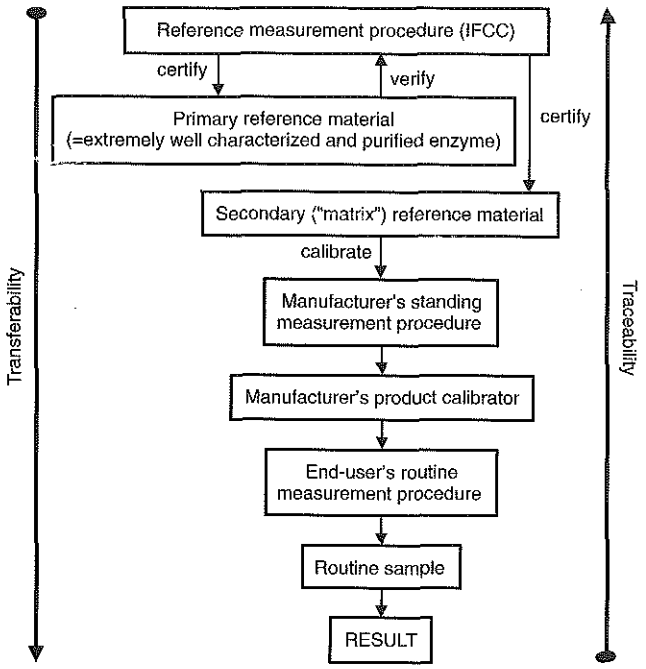

Figure 8-12 The proposed reference system for enzyme measurement showing the traceability of the laboratory result to the reference measurement procedure. *(From Panteghini et al, Clin Chem Lab Med 2001;39:795-800. Reprinted with permission of Walter de Gruyter.)*

Optimization, Standardization, and Quality Control

To measure enzyme activity reliably, all the factors that affect the reaction rate—other than the concentration of active enzyme—must be optimized and rigidly controlled. Furthermore, because the reaction velocity is at or near its maximum under optimal conditions, a larger analytical signal is obtained that can be more accurately and precisely measured than a smaller signal obtained under suboptimal conditions. Much effort has therefore been devoted to determining optimal conditions for measuring the activities of enzymes of clinical importance.

Optimization

Optimization of reaction conditions for enzyme assays has traditionally been carried out by varying a single factor and studying its effect on the reaction rate, then repeating the experiment with a second factor and so on until effects of all the variables have been tested. An optimal combination of variables is selected on the basis of these experiments, and the validity of the chosen conditions is verified. Not only is this approach labor intensive, but it also is not well adapted to situations in which the effects of different variables are interdependent, as is frequently the case in enzyme analysis. This traditional empirical approach to optimization has been replaced by newer techniques of simplex cooptimization and response-surface methodology.[11]

Standardization

Despite considerable effort, the goal of a single universally used procedure to measure the catalytic activity of a given enzyme has not been achieved. Consequently, current enzyme standardization efforts are focused on the development of a system that provides for comparability of test results, independent of the measurement method. To achieve this, a "reference system" based on the concepts of metrological traceability and of hierarchy of analytical methods has been proposed.[10] A reference procedure and certified reference materials are the basis of the metrological traceability chain (Figure 8-12). As part of this hierarchy, reference procedures at 37 °C for the most common enzymes have been developed and a group of reference laboratories are being selected to perform the measurements at an appropriately high metrological level.[12–17]

Reference procedures set standards of precision and accuracy against which the relative performances of methods intended for routine use can be judged. The reference procedure is used to assign a certified value to the reference material. This certified material can then be used by the manufacturers to assign values to commercial calibrators resulting in traceability of the value obtained in the laboratory.

Several studies have demonstrated that enzyme preparations with reproducible properties and purity and having assured stability can be made. These may be from animal sources in which the enzymes closely resemble their human counterparts, although new possibilities have been created by gene-transfer and mass-cell culture techniques ("recombinant" proteins).

For a reference system to be capable of standardizing the results of different assays of a given enzyme activity, some conditions must be satisfied.[8] First, the reference procedure used to assign the value of the reference material and the routine method(s) to be calibrated must have identical specificities for the analyte enzyme (i.e., for the specific isoenzyme or isoform under study). Second, the properties of the calibrator material must be the same as or closely similar to those of the analyte enzyme in its natural matrix, typically serum (i.e., the material must be "commutable" with human serum samples for that particular method).

Quality Control

Despite various difficulties, systematic application of quality control programs is as essential in enzyme analysis as in other forms of clinical analysis if the results obtained are to be useful in diagnosis and treatment.

The application of quality control procedures to ensure that satisfactory analytical performance of enzyme assays is maintained on a day-to-day basis is complicated by the tendency of enzyme preparations to undergo denaturation with loss of activity. This makes it difficult to distinguish between poor analytical performance and denaturation as possible causes of a low result obtained for a control sample introduced into a batch of analyses. Assured stability within a defined usable time span is therefore the prime requirement for enzyme control materials, as it is for enzyme calibrators. However, specifications for the two types of materials can differ in other respects. Because the function of a calibrator is to provide a stated activity under defined assay conditions, it is not necessary for it to show sensitivity to changes in the assay system identical to those of the samples under test; therefore within certain limits, enzymes from various sources can be considered in the search for stability. However, it is the function of a *control* to reveal small variations in reaction conditions, so it must mimic the samples being analyzed. The preparation of enzymes from human sources is not by itself a guarantee of an effective control. For example, human placental ALP is very stable, but it differs significantly in kinetic properties from the liver and bone enzymes that contribute most of the ALP activity of human serum samples; it is therefore not an ideal enzyme for use in control material for the determination of ALP.

Lyophilized and liquid preparations containing various enzymes are available from commercial sources, and these have a useful function in quality control. Serum pools can also be prepared in the laboratory for quality control purposes (with care to exclude any specimens contaminated with hepatitis virus or human immunodeficiency virus), then assayed for enzyme activity and stored in a freezer in small portions for daily use.

Measurement of Enzyme Mass Concentration

A number of immunoassays for human enzymes and isoenzymes measuring protein mass instead of catalytic activity have been described. To develop such assays, purified enzyme protein has to be prepared to act as a calibrator, to be labeled, and to be used to raise the enzyme-specific antibody. These methods determine all molecules with the antigenic determinants necessary for recognition by the antibody so that inactive enzyme molecules that are immunologically unaltered are measured along with active molecules. This has been found to be significant in the determination of some digestive enzymes, such as trypsin, when inactive precursors and inhibitors of catalytic activity are present in plasma. In the majority of cases, however, no degradation or changes of the active enzyme occur in blood so that clinical equivalence of the different measurement approaches (i.e., estimation of catalytic activity and mass concentration) can be obtained.

In practice, however, immunoassays have not been widely used for the determination of total enzyme activities for diagnostic purposes as these assays generally cannot compete in speed, precision, and costs with automated measurement of total catalytic activity. Furthermore, several enzyme activities in serum are due to mixtures of immunologically distinct isoenzymes, so an assay using a single type of antibody usually determines only one of the enzyme forms. However, this disadvantage in the determination of total enzyme activity becomes a marked advantage in the measurement of specific isoenzymes and isoforms, and immunological methods have assumed great importance in isoenzyme analysis for diagnostic purposes.

Enzymes as Analytical Reagents

Enzymes are used as analytical reagents for the measurement of several metabolites and substrates and in immunoassays to detect and quantitate immunological reactions.

Measurement of Metabolites

The use of enzymes as analytical reagents to measure metabolites frequently offers the advantage of great specificity for the substance being determined. This high specificity typically removes the need for preliminary separation or purification stages, so the analysis can be carried out directly on complex mixtures such as serum. Uricase (urate oxidase), urease, and glucose oxidase are examples of highly specific enzymes used in clinically important assays, such as the measurement of uric acid, urea, and glucose in biological fluids. However, high specificity cannot always be achieved in practice, and knowledge of the substrate specificities of reagent enzymes is therefore essential to allow possible interferences with the assay to be anticipated and corrected. Coupled reactions are often used to construct an enzymatic analytical system for determining a particular compound, because they are in measurements of enzyme activity, and the specificity of the coupled reactions may modify the specificity of the overall process. An example of this is the determination of glucose by the hexokinase reaction. Hexokinase converts sugars other than glucose to their 6-phosphate esters. However, the indicator reaction

used to monitor this change is catalyzed by glucose-6-phosphate dehydrogenase, an enzyme that is highly specific for its substrate; so the overall process is highly specific for glucose.

In practice, both equilibrium and kinetic (rate) methods have been developed that use enzymes as reagents.

Equilibrium Methods

For most assays used to determine the amount of a substance enzymatically, they are allowed to continue to completion so that all the substrate has been converted into a measurable product. These methods are called *end point* or, more correctly, *equilibrium* methods, because the reaction ceases when equilibrium is reached. Reactions in which the equilibrium point corresponds virtually to complete conversion of the substrate are obviously preferable for this type of analysis. However, unfavorable equilibriums can often be displaced in the desired direction by additional enzymatic or nonenzymatic reactions that convert or "trap" a product of the first reaction (e.g., in measuring lactate with lactate dehydrogenase, the pyruvate formed can be trapped by the addition of hydrazine, with which it forms an irreversible hydrazone.)

Theoretically the time required to transform a fixed quantity, Q, of substrate into products is inversely proportional to the amount of enzyme, $[E]$, present.

$$Q = k_1 + [E] \times t \tag{24}$$

and

$$[E] = \frac{Q}{k_1} \times \frac{1}{t} \tag{25}$$

where k_1 is the rate constant and t is the elapsed time. Equilibrium methods may therefore require the use of appreciable amounts of enzyme for each sample to avoid inconveniently long incubation periods. As the substrate concentration falls to low levels toward the end of the reaction, the K_m of the enzyme becomes important in determining the reaction rate. Enzymes with high affinities for their substrates (low K_m values) are therefore most suitable for equilibrium analysis. Equilibrium methods are largely insensitive to minor changes in reaction conditions. It is not necessary to have exactly the same amount of enzyme in each reaction mixture or to maintain the pH or temperature absolutely constant, provided that the variations are not so great that the reaction is not completed within the fixed time allowed.

Kinetic Methods

First- or pseudo–first-order reactions are the most important reactions for the kinetic determination of substrate concentration. For any first-order reaction, the substrate concentration $[S]$ at a given time t after the start of the reaction is given by

$$[S] = [S_0] \times e^{-kt} \tag{26}$$

where $[S_0]$ is the initial substrate concentration, e is the base of the natural log, and k is the rate constant.

The change in substrate concentration $\Delta[S]$ over a fixed-time interval, t_1 to t_2, is related to $[S_0]$ by the equation

$$[S_0] = \frac{-\Delta[S]}{e^{-kt_1} - e^{kt_2}} \tag{27}$$

As this equation indicates, the change in substrate concentration over a fixed time interval is directly proportional to its initial concentration. This is a general property of first-order reactions.

For an enzymatic reaction, first-order kinetics are followed when $[S]$ is small compared with K_m. Thus,

$$v = \frac{V_{max}}{K_m} \times [S] \tag{28}$$

or

$$v = k[S] \tag{29}$$

Thus, the first-order rate constant, k, is equal to $\frac{V_{max}}{K_m}$.

Methods in which some property related to substrate concentration (such as absorbance, fluorescence, chemiluminescence, etc.) is measured at two fixed times during the course of the reaction are known as *two-point* kinetic methods. They are theoretically the most accurate for the enzymatic determination of substrates. However, these methods are technically more demanding than equilibrium methods and all the factors that affect reaction rate, such as pH, temperature, and amount of enzyme, must be kept constant from one assay to the next, as must the timing of the two measurements. These conditions can readily be achieved in automatic analyzers. A reference solution of the analyte (substrate) must be used for calibration. To ensure first-order reaction conditions, the substrate concentration must be low compared to the K_m (i.e., in the order of less than $0.2 \times K_m$. Enzymes with high K_m values are therefore preferred for kinetic analysis to give a wider usable range of substrate concentration.

Immunoassay

In enzyme immunoassay, enzyme-labeled antibodies or antigens are first allowed to react with ligand, and then an enzyme substrate is subsequently added. ALP, horseradish peroxidase, glucose-6-phosphate dehydrogenase, and β-galactosidase have all been used as enzyme labels. A modification of this methodology is the enzyme-linked immunoabsorbent assay (ELISA) in which one of the reaction components is bound to a solid-phase surface. In this technique, an aliquot of sample is allowed to interact with the solid-phase antibody. After washing, a second antibody labeled with enzyme is added to form an Ab-Ag-Ab-enzyme complex. Excess free enzyme-labeled antibody is then washed away and the substrate is added; the conversion of substrate is proportional to the quantity of antigen. In

immunoassays, it is not the specificity of enzymes that is important but their sensitivity.

Analytical Applications of Immobilized Enzymes

The consumption of relatively expensive enzymes, one of the disadvantages of enzymatic analysis, can be reduced by the use of immobilized enzymes that can be reused for several analyses. Immobilized enzymes have been chemically bonded to adsorbents, such as microcrystalline cellulose, diethylaminoethyl (DEAE) cellulose, carboxymethyl cellulose, and agarose. Diazo, triazine, and azide groups are used to join the enzyme protein to the insoluble matrix, forming either particles in contact with the substrate solution or a surface in contact with substrate solution, such as a membrane or a coating on the inner surface of a vessel holding the substrate solution. Among enzymes available in such immobilized form are urease, hexokinase, α-amylase, glucose oxidase, trypsin, and leucine aminopeptidase. Stability to heat and other forms of inactivation is considerably increased compared with enzymes in solution. Immobilized proteolytic enzymes are not subject to autodigestion. However, some properties of the enzyme, such as its K_m or its pH optimum, may be altered.

Techniques such as potentiometry, polarography, and microcalorimetry have been chosen in exploiting the benefits of immobilized enzymes (see Chapter 4). Enzymes incorporated into membranes form part of enzyme electrodes. The surface of an ion-sensitive electrode is coated with a layer of porous gel in which an enzyme has been polymerized. When the electrode is immersed in a solution of the appropriate substrate, the action of the enzyme produces ions to which the electrode is sensitive. For example, an oxygen electrode coated with a layer containing glucose oxidase can be used to determine glucose by the amount of oxygen consumed in the reaction, and urea can be estimated by the combination of a selective ammonium ion–sensitive electrode and a urease membrane.

Measurement of Isoenzymes and Isoforms

A number of analytical techniques have been used to measure isoenzymes or isoforms. They include *electrophoresis* (see Chapter 5), *chromatography* (see Chapter 6), chemical inactivation, and differences in catalytic properties, but the most common routine methods are now based on immunochemical methods.

Electrophoresis

Isoelectric focusing (see Chapter 5), has been used successfully to separate isoenzymes that differ in the amount of covalently bound sugar residues, such as sialic acid.

Chromatography

Ion-exchange chromatography makes use of differences in net molecular charge at a given pH to separate isoenzymes. A typical ion-exchange material is DEAE cellulose, in which ionizable DEAE groups are attached to an inert cellulose matrix. Ion-exchange chromatography is not in general as highly resolving of closely similar proteins as is zone electrophoresis, but relatively large amounts of proteins can be separated with good recoveries of enzymatic activity, so the method is of great value in enzyme purification.

Other forms of chromatography that have been applied to fractionation of isoenzyme mixtures include high-performance liquid chromatography (HPLC) and affinity chromatography. The latter makes use of differences between isoenzymes in their affinities for a specific ligand that is attached to an inert insoluble support used as the stationary phase in a chromatography column or in a batch technique.

Chemical Inactivation and Differences in Catalytic Properties

Selective inactivation under controlled conditions has been used in the past in isoenzyme characterization. The method is based on differences in stability that result from small changes in the structure of protein molecules. Elevated temperatures or concentrated solutions of urea or other reagents were used to denature the enzyme. Rates of enzyme inactivation by these agents are critically dependent on the conditions of the experiment, which must therefore be strictly controlled if reliable comparisons between samples are to be made.

Differences in catalytic properties, such as differences in K_m, relative rates of reaction with substrate analogues (when the specificity of the enzyme allows for variation in the structure of the substrate), pH optima, and response to inhibitors, typically exist between isoenzymes that are the products of multiple gene loci. These differences can be made the basis of methods of identification and measurement of particular isoenzymes.

Immunochemical Assays

Immunochemical methods of isoenzyme analysis are particularly applicable to isoenzymes derived from multiple gene loci, because these are usually most clearly antigenically distinct. However, the greater discriminating power of monoclonal antibodies has potentially brought all multiple forms of an enzyme within the scope of immunochemical analysis. Some of these methods make use of catalytic activity of the isoenzymes. For example, residual activity may be measured after reaction with antiserum. Radioimmunoassays, in which isoenzyme labeled with a radioactive tracer competes with unlabeled isoenzyme for antibody-binding sites, have also been applied to isoenzyme measurement. These methods do not depend on the catalytic activity of the isoenzyme being determined. However, with the development of automated immunoassay systems, the most common routine methods for measuring isoenzymes, such as CK-MB, are solid phase enzyme-linked immunosorbent assays (ELISA).

The choice and application of various methods of isoenzyme analysis in clinical enzymology are discussed in Chapter 21 in relation to specific isoenzyme systems.

DIAGNOSTIC ENZYMOLOGY

In general, clinical laboratorians are principally concerned with changes in the activity in the serum or plasma of enzymes that are predominantly intracellular and that are normally present in the serum at low activities only. By measuring changes in the activities of these enzymes in disease, they attempt to infer the location and nature of pathological changes in the tissues of the body. Therefore understanding the factors that affect the rate of release of enzymes from their cells of origin and the rate at which they are cleared from the circulation is necessary so that changes in activity in disease can be interpreted correctly.

Factors Affecting Enzyme Levels in Plasma or Serum[4,5]

The measured level of activity of an enzyme in blood is the result of the balance between the rate at which it is entering the circulation from its cells of origin and the rate at which it is removed.

Entry of Enzymes into the Blood

The measured levels of an enzyme in blood are the result of the balance between the rate at which it enters the circulation from its cells of origin and the rate at which it is inactivated or removed.

Leakage of Enzymes from Cells

Enzymes are retained within their cells of origin by the plasma membrane surrounding the cell. The plasma membrane is a metabolically active part of the cell, and its integrity depends on the cell's production of ATP. Any process that impairs ATP production, either by depriving the cell of oxidizable substrates or by reducing the efficiency of energy production by restricting the access of oxygen (ischemia or anoxia), promotes deterioration of the cell membrane. The earliest sign of impaired energy metabolism is the efflux of potassium and influx of sodium; water thus accumulates within the cell, causing it to swell. The next and most serious stage is the entry of Ca^{2+}, which stimulates intracellular enzymes, leading to both cell damage and disruption of the cell membrane. Finally, free radicals formed during these processes may cause further damage. The membrane becomes leaky; if cellular injury becomes irreversible, the cell will die, although enzyme loss may also occur without irreversible injury occurring. Small molecules are the first to leak from damaged or dying cells, followed by larger molecules, such as enzymes and other proteins. Cytosolic proteins appear early on in the plasma, followed much later by mitochondrial and membrane-bound enzymes. Ultimately, the contents of the now necrotic cells are discharged.

Because of the very high concentrations of enzymes within the cell—thousands or even tens of thousands of times greater than the concentrations in extracellular fluid—and because extremely small amounts of enzyme can be detected by their catalytic activity, an increase of enzyme activity in the extracellular fluid or plasma is an extremely sensitive indicator of even minor cellular damage, some causes of which are listed in Table 8-2.

Direct attack on the cell membranes by such agents as viruses or organic chemicals also causes enzyme release and

TABLE 8-2 Causes of Cell Damage or Death

Category	Examples
Hypoxia (an extremely common accompaniment of clinical disease)	Loss of blood supply due to narrowing (atheromatous plaques) or blocking (thrombosis) of artery or vein; ischemic-perfusion injury; inadequate oxygenation due to cardiorespiratory failure; loss of oxygen-carrying capacity, CO poisoning, and anemia
Chemicals and drugs (an important cause of cellular damage)	Environmental pollutants—lead, mercury; drugs—use and abuse; alcohol; tobacco
Physical agents	Trauma; extremes of heat and radiation; electrical energy; toxic chemicals
Microbiological agents	Bacteria, viruses, fungi, protozoa, and helminths
Immune mechanisms	Immune disorders can cause tissue damage by a number of mechanisms: 1. Anaphylaxis (causing release of vasoactive amines) 2. Cytotoxicity (causing the target cell to be lysed) 3. Immune complex disease (leading to release of lysosomal enzymes) 4. Cell-mediated hypersensitivity (leading to cytotoxicity)
Genetic defects	Disorders with polygenic inheritance—diabetes mellitus, gout Mendelian disorders—X-linked disorders, autosomal dominant and recessive disorders, disorders with variable modes of transmission
Nutritional disorders	Protein-calorie malnutrition, vitamin deficiencies, mineral deficiencies; obesity and its consequences

Based on the classification of Robbins and colleagues. In: Basic pathology, 3rd ed. Philadelphia: WB Saunders, 1981.

one that is particularly important in the case of the liver. A reduction in the supply of oxygenated blood perfusing any tissue will also promote enzyme release. An example of a clinical condition in which such a reduction occurs is myocardial infarction. The cells of the affected region rapidly begin to deteriorate and die, releasing their enzyme contents to the systemic circulation, which accounts for the rapid rise in serum enzyme activity that is characteristic of this condition. The liver is very sensitive to hypoxia, which results from diminished cardiac output (heart failure). Increased activities of hepatocellular enzymes in the blood accompany a wide variety of conditions, such as congestive heart failure, shock, and hypoxemia.

Skeletal muscles also contribute enzymes to blood. Again, the cause may be poor perfusion, hypothermia, or direct trauma to the muscles (crush injuries). Infection, inflammation (polymyositis), degenerative changes (dystrophies), drugs, and alcohol (alcoholic myopathy) will cause enzyme leakage from myocytes. Enzyme release from muscles and other tissues also occurs as a result of anesthesia.

Efflux of Enzymes from Damaged Cells

Once the conditions for leakage of enzymes from cells have become established, the speed and extent with which the process is reflected in enzyme changes in the blood depend on several factors.

The driving force of enzyme release is the steep concentration gradient of enzyme activity that exists between the interior and the exterior of the cells. The rate of escape of enzyme molecules is presumably controlled to some extent by diffusion; therefore, smaller enzyme molecules might be expected to appear in the extracellular fluid earlier than larger ones. Although this is probably true to some extent, the range of molecular weights covered by enzymes of diagnostic interest is rather narrow, so this factor may be less important.

The way in which released enzyme molecules are transferred from the interstitial fluid to the blood varies from one tissue to another, passing directly through the capillary wall or by lymphatic transfer. Direct transfer probably occurs to a large extent in the liver, which is a highly vascular tissue with many permeable capillaries, although there is some evidence that liver enzymes may also be subject to lymphatic transfer. On the other hand, the capillaries of skeletal muscle are relatively impermeable, and in this tissue it is probable that released enzymes mainly reach the circulatory system by way of drainage from the lymphatic system. Lymph drainage is also important in transporting enzymes released from damaged intestinal and myocardial cells to the circulation although a considerable proportion of myocardial enzymes also reaches the circulation by direct capillary transfer following infarction.

The intracellular location of the leaking enzymes also affects the rates at which they appear in the circulation. As would be expected, the most sensitive indicators of cell damage are the enzymes that are present in the soluble fraction of the cell. Enzymes associated with subcellular structures, such as mitochondria, are less readily released into the circulation. This fact has been used in attempts to distinguish reversible leakage, presumed to reflect damage only to the cell membrane, from necrotic lesions in which the intracellular structures are destroyed.

The relation between tissue injury and the appearance of enzymes in the circulation is most clearly seen in the condition of myocardial infarction, in which a relatively short episode of damage is followed by a rapid transfer of enzymes to the circulatory system. About 24 hours after a myocardial infarction, the pattern of relative activity of various enzymes in the circulatory system closely resembles that in the myocardial tissue. These relationships are less clearly recognized in other conditions, such as chronic liver disease, in which enzyme release is a process that continues for a period of time. The pattern of relative enzyme activities in serum in chronic disease may also become distorted by differential rates of removal of enzymes from the circulation and possibly also by differential changes of rates of enzyme synthesis in the affected tissue.

Some of the small amounts of intracellular enzymes normally present in the plasma can be assumed to result from wear and tear of cells or overflow of enzyme from healthy cells. This contribution of enzymes to the circulating blood may decrease, either as the result of a genetic deficiency of enzyme production (e.g., as is the case for ALP in hypophosphatasia or in individuals homozygous for the "silent" gene for serum cholinesterase), or when enzyme production is depressed as a result of disease (e.g., the production of serum cholinesterase is often depressed in liver disease).

Release of enzymes from damaged or dying cells and changes in the rate of enzyme production constitute the most important mechanisms by which changes in enzyme activity in the serum or plasma are produced. However, other possibilities exist and appear to account for some changes of diagnostic importance. For example, much of the γ-glutamyl transferase activity of liver cells is located on their exterior surfaces. It is possible that ectoenzymes, such as this, may be eluted from the surfaces, especially where there is increased detergent action of the blood through accumulation of bile salts. This process does not involve cell damage in the sense of increased membrane permeability, as evidenced by the lack of correlation between the activities of γ-glutamyl transferase and aminotransferases in serum in liver diseases of different types.

Altered Enzyme Production

The small amounts of intracellular enzymes normally present in plasma are thought to result from turnover of cells or leakage of enzymes from healthy cells. This contribution of enzymes to the circulating blood may decrease either as the result of a genetic deficiency of enzyme production or when enzyme production is depressed as a result of disease. However, cases in which enzyme production is increased are

of more general interest in diagnostic enzymology. For example, an increase in the number and activity of the ALP producing osteoblasts of bone is responsible for the increased level of ALP in the serum of normally growing children. Increased osteoblastic activity also accounts for the increased levels of this enzyme in serum in various types of bone disease. Toward the end of normal pregnancy, the placenta constitutes a new source of ALP and contributes its characteristic isoenzyme to the maternal circulation.

The process of enzyme induction also increases enzyme production. An example of such induction is the increased activity of γ-glutamyltransferase in serum, which results from the administration of drugs such as barbiturates or phenytoin, and from the intake of ethanol. Biliary obstruction induces increased synthesis of ALP in the liver.

Clearance of Enzymes

Significant evidence is now available about the way in which enzymes are cleared from circulation. Few enzyme molecules are small enough to pass through the healthy glomerulus of the kidney; therefore urinary excretion is not a major route for elimination of enzymes from circulation. An exception to this is α-amylase; increased concentrations of this enzyme in the blood (e.g., after *acute pancreatitis*) are accompanied by increased excretion in the urine. Evidence now suggests that many enzymes are probably not inactivated in the plasma, but that they are rapidly removed, probably by the reticuloendothelial system, such as the bone marrow, spleen, and liver (Kupffer's cells) or, to a lesser extent, by nearly all cells in the body. The mechanism appears to be by receptor-mediated endocytosis (the process of recognition, specific accumulation, and uptake of protein by specific cell-surface receptors followed by fusion with the lysosomes, digestion of the ingested protein, and recycling of the receptor back to the cell membrane). For example, hepatic Kupffer's cells have been shown to take up several tissue-derived enzymes—such as LD-5, CK-MM, adenylate kinase, cytoplasmic and mitochondrial aspartate aminotransferase, and malate and alcohol dehydrogenases—by receptor-mediated endocytosis, which may have affinity for the lysine residues on these enzymes. The adult isoform of intestinal ALP is a galactosyl-terminal glycoprotein that reacts with a galactosyl-specific receptor on the hepatocyte membrane and undergoes subsequent endocytosis. This process is rapid, accounting for the extremely short plasma half-life of this isoform. However, in hepatic cirrhosis, in which considerable reduction in parenchymal cell mass often occurs, the plasma concentration and half-life of the isoform increase. Other ALP isoenzymes and isoforms are sialoglycoproteins that do not react with the galactosyl receptor and are therefore protected from rapid uptake from blood. Indeed, many examples are now known of excessive sialylation of ALPs, produced by malignant cells, prolonging their plasma half-lives and facilitating their detection. This example illustrates the importance of understanding the processes by which enzymes are cleared from plasma.

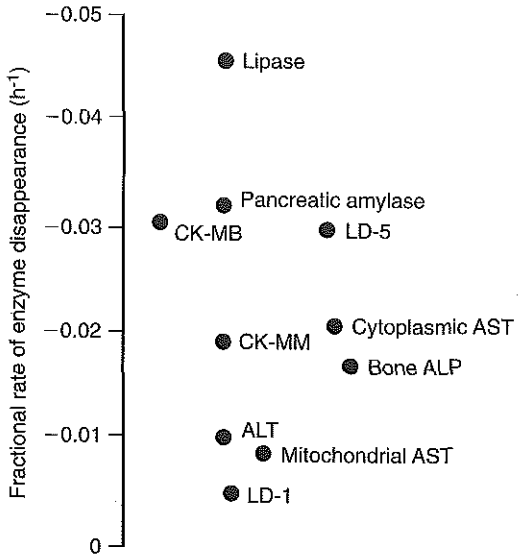

Figure 8-13 Fractional disappearance rates (k_d) from human blood of the most important enzymes.

The half-lives of enzymes in plasma vary from a few hours to several days, but in most cases, with an average half-life ($t_{1/2}$) of 6 to 48 hours. Rates of decay may also be expressed as k_d values—the fractional disappearance rate—and the relationship to $t_{1/2}$ values is:

$$k_d = 2.303 \log \frac{2}{t_{1/2}} = \frac{0.693}{t_{1/2}} \qquad (30)$$

Typical disappearance rates from human blood for several clinically relevant enzymes are shown in Figure 8-13.

Selection of Enzyme Tests

The selection of which enzyme to measure in serum for diagnostic or prognostic purposes depends on a number of factors. An important factor is the distribution of enzymes among the various tissues, shown, for example, for aspartate aminotransferase, alanine aminotransferase, and creatine kinase in Figure 8-14. The main enzymes of established clinical value, together with their tissues of origin and their major clinical applications, are listed in Table 8-3 (see also Chapter 21).

The mass of the damaged or malfunctioning organ, together with the enzyme cell/blood gradient, obviously has a profound influence on the resulting elevation of enzyme activity in blood. Thus the gradient of activity of prostatic acid phosphatase between prostate and blood is about $10^3:1$, and the mass of that organ is 20 g. By contrast, the cell and/or blood gradient of alanine aminotransferase in the liver cell is $10^4:1$, and the mass of the liver can exceed 1000 g. Obviously, fewer cells have to be damaged in the liver than in the prostate for the abnormality to be detected by an enzyme elevation in blood. If on the other hand there is total

TABLE 8-3 Distribution of Diagnostically Important Enzymes

Enzyme	Principal Sources of Enzyme in Blood	Principal Clinical Applications
Alanine aminotransferase	Liver, skeletal muscle	Hepatic parenchymal disease
Alkaline phosphatase	Liver, bone, intestinal mucosa, placenta	Bone diseases, hepatobiliary diseases
Amylase	Salivary glands, pancreas	Pancreatic diseases
Aspartate aminotransferase	Liver, skeletal muscle, heart, erythrocytes	Hepatic parenchymal disease, muscle disease
Cholinesterase	Liver	Organophosphorus insecticide poisoning, suxamethonium sensitivity, hepatic parenchymal diseases
Creatine kinase	Skeletal muscle, heart	Muscle diseases, myocardial infarction
Glutamate dehydrogenase	Liver	Hepatic parenchymal diseases
γ-Glutamyltransferase	Liver, kidney	Hepatobiliary diseases
Lactate dehydrogenase	Heart, liver, skeletal muscle, erythrocytes, platelets, lymph nodes	Hemolysis, hepatic parenchymal diseases, myocardial infarction
Lipase	Pancreas	Pancreatic diseases
5′-Nucleotidase	Hepatobiliary tract	Hepatobiliary disease
Trypsin(ogen)	Pancreas	Pancreatic diseases

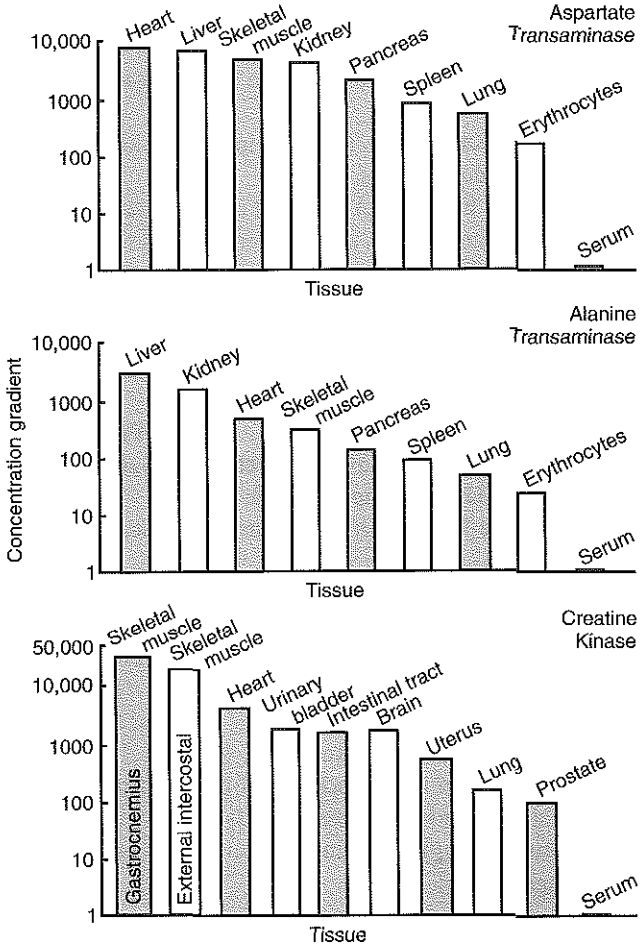

Figure 8-14 The concentration gradients between some human tissues and serum for aspartate transaminase, alanine transaminase, and creatine kinase. The concentration gradient axis is logarithmic.

organ involvement, then clearly the vast number of affected liver cells will markedly elevate blood concentrations of any liver enzyme. It has been estimated that if only 1 liver cell in every 750 is damaged, elevation in the blood level of alanine aminotransferase would be detectable.

Knowledge of the intracellular location of enzymes can assist in determining the nature and severity of a pathological process if suitable enzymes are assayed in the blood. For instance, a mild, reversible viral inflammation of the liver, such as a mild attack of viral hepatitis, is likely to increase only the permeability of the cell membrane and allow cytoplasmic enzymes to leak out into the blood, whereas a severe attack causing cell necrosis also disrupts the mitochondrial membrane, and both cytoplasmic and mitochondrial enzymes are detected in the blood. Finally, in selecting a suitable enzyme to assay in blood for diagnostic purposes, the rate at which its activity disappears from the blood is of significance. As previously indicated, the most commonly assayed enzymes are those with half-lives in the range of 12 hours or greater.

CHAPTER 9

Principles of Immunochemical Techniques*

L.J. Kricka, D.Phil., F.A.C.B., C.Chem., F.R.S.C., F.R.C.Path.

Immunochemical reactions form the basis of a diverse range of sensitive and specific clinical assays. In a typical immunochemical analysis, an antibody is used as a reagent to detect an antigen of interest. The exquisite specificity and the high affinity of antibodies for specific antigens, coupled with the unique ability of antibodies to cross link antigens, allow the identification and quantitation of specific substances by a variety of methods. The principles of the methods most commonly used in the laboratory are discussed in this chapter. This introduction is intended to acquaint the reader with the structure and function of antibodies (immunoglobulins) in relation to their use as reagents in immunoanalyses.

BASIC CONCEPTS

The binding of antibodies and their complementary antigens forms the basis of all immunochemical techniques.

ANTIBODIES

Antibodies are immunoglobulins that are capable of binding specifically to a wide array of natural and synthetic antigens, including proteins, carbohydrates, nucleic acids, lipids, and other molecules. Immunoglobulins consist of five general classes designated as IgG, IgA, IgM, IgD, and IgE. Immunoglobulin G is the most prevalent immunochemical reagent in use. Currently, immunoglobulins A, M, D, and E do not play an important role in immunochemical analysis. A schematic diagram of the IgG molecule is shown in Figure 9-1. IgG is a glycoprotein (MW 158,000) composed of two duplex chains with each set being made up of a heavy (γ) and light (κ and λ) chain joined by disulfide bonds. Interchain disulfide bonds hold the duplex chains together and create a symmetrical molecule. For more information on immunoglobulins, see Chapter 20.

The variable amino acid sequence at the amino terminal end of each chain determines the antigenic specificity of the particular antibody. Each unique amino acid sequence is a product of a single plasma cell line or clone. The normal host response to an immunogen* results in the stimulation of one or two major classes of lymphocytes that are able to divide and produce plasma cells capable of secreting antibodies. Each plasma cell line produces antibodies with a single specificity. A complex antigen is capable of eliciting a multiplicity of antibodies with different specificities that are derived

*The author gratefully acknowledges the original contribution by Dr. Gregory Buffone, upon which portions of this chapter are based.

*An *immunogen* is any chemical substance capable of inducing an immune response. The term immunogen is now used instead of the term *antigen* when referring to materials capable of eliciting antibody formation when injected into a host. The term *antigen* is used for any material capable of reacting with an antibody, without necessarily being capable of inducing antibody formation. For example, egg albumin is an immunogen, because it is capable of inducing formation of antiegg albumin antibody. Because it will react with antimorphine antibodies, morphine is an antigen. However, it is not an immunogen, because it does not induce antibody formation unless first conjugated with a protein.

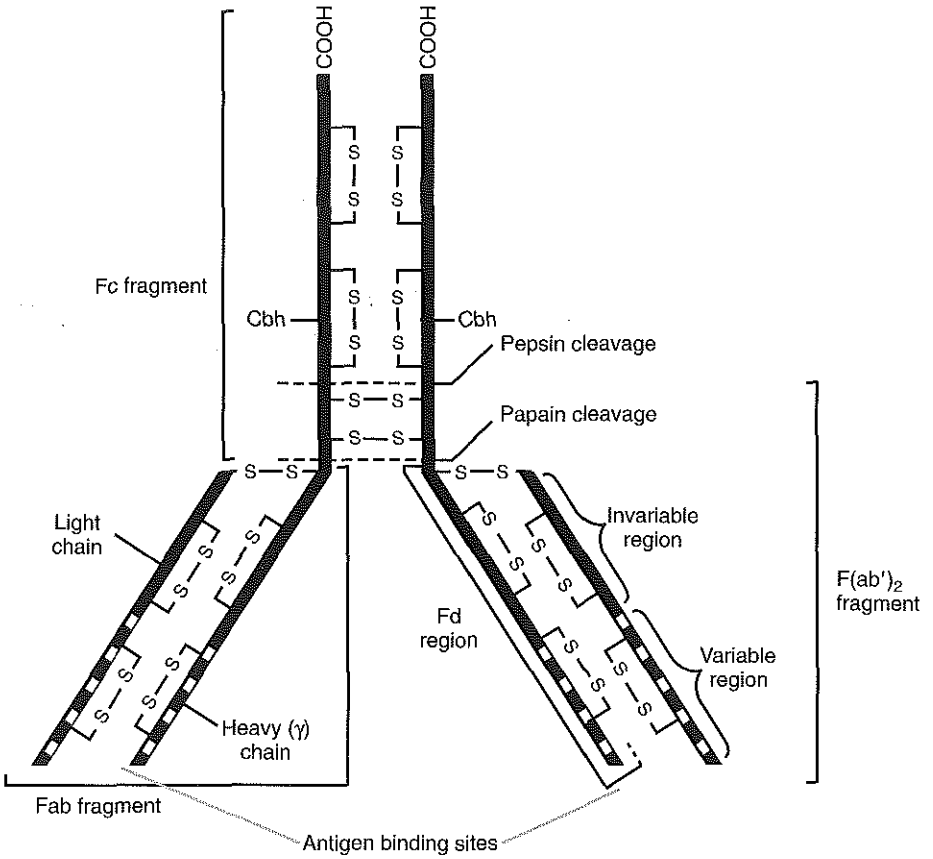

Figure 9-1 Schematic diagram of IgG antibody molecule showing carbohydrate (Cbh), disulfide bonds (—S—S—), and major fragments produced by proteolytic enzyme treatment ($F[ab']_2$, Fc, Fab, Fd).

from different cell lines. Antibodies derived in this manner are termed *polyclonal* and exhibit diverse specificities in their reactivity with the immunogen. Each unique region of the antigen molecule that will bind a complementary antibody is termed an *epitope* (antigenic determinant).

Immunogens

An *immunogen* is either a protein or a substance coupled to a carrier, usually a protein, that when introduced into a foreign host is capable of inducing the formation of an antibody in the host. The route of introduction of the immunogen is usually, but not always, intradermal. The antibody produced may be either circulating *(humoral)* or tissue bound *(cellular)*, as in delayed hypersensitivity reactions or graft host reactions.

A *hapten* is a chemically defined determinant that when conjugated to an immunogenic carrier stimulates the synthesis of antibody specific for the hapten. It is capable of binding an antibody but cannot by itself stimulate an immune response. Natural immunogens are usually more complex than haptens and have several epitopes. Such immunogens are capable of reacting with several antibodies, allowing cross-linking and the formation of large immune complexes. In addition to proteins and polypeptides, lipids (such as the Wasserman antigen and cardiolipin), nucleic acids (e.g., double-stranded deoxyribonucleic acid [dsDNA]), and many other materials function as antigens. Some general properties required for immunogenicity include: (1) areas of structural stability within the molecule, (2) randomness of structure, (3) a minimal molecular weight of 4000 to 5000, (4) ability to be metabolized (a necessary but not sufficient criterion for some classes of antigens), (5) accessibility of a particular immunogenic configuration to the antibody-forming mechanism, and (6) the foreignness of structure to the host. The overall shape and charge of the molecule in most cases have very little influence on the ability to induce antibody formation.

Injection of an immunogen into a host animal induces a series of biological changes leading to markedly increased production of certain serum globulins with specific antibody activity—the immunoglobulins—and to changes in the capability of certain cellular elements to give an immune response. Continued stimulation by an immunogen results in increasing production of immunoglobulins of different types and of different binding characteristics for antigens. In some cases excessive stimulation leads to immunological

paralysis in which no antibody response is mounted until a major fraction of the immunogen is cleared from the organism. After the first exposure to an immunogen, a latent period (induction) occurs during which no antibody is present in serum; this period may last from 5 to 10 days. Because antibody formation by sensitized (immunogen coated) cells can be demonstrated in vitro in a period of minutes, the long delay in antibody build up in vivo is caused by the time required for transport of immunogen to the site of antibody production, for transmission of information, and for actual synthesis of the antibody.

The strength or energy of interaction between the antibody and antigen is described by two terms. *Affinity* refers to the thermodynamic quantity defining the energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen. *Avidity* refers to the overall strength of binding of an antibody and an antigen and includes the sum of the binding affinities of all the individual combining sites on the antibody. For example, IgG has two affinity-binding sites, whereas IgM has 10 affinity-binding sites per antibody molecule. Thus affinity is a property of the substance bound (antigen), and avidity is a property of the binder (antibody). For polyclonal antibodies, avidity is difficult to determine primarily because of the diversity of the antibody population.

Polyclonal antiserum is raised in a normal animal host in response to immunogen administration. In contrast, *monoclonal antiserum* is produced in a very different manner and represents the product of a single clone or plasma cell line rather than a heterogeneous mixture of antibodies produced by many cell clones in response to immunization. Monoclonal antibodies are now widely used as reagents in immunoassay techniques.[45,61] The usual method of production of monoclonal antibodies involves fusing sensitized lymphocytes from the spleens or lymph nodes of mice that have been immunized once or more over a 2- to 4-week period with a murine myeloma cell line from tissue culture in the presence of polyethylene glycol (PEG), which promotes cell fusion through an unknown mechanism. The murine myeloma cell line is an immortal B-cell line. The murine myeloma cell lines most commonly used are deficient in the enzyme hypoxanthine guanine phosphoribosyl transferase (HGPRT) and therefore cannot synthesize purine bases from thymidine and hypoxanthine in the presence of aminopterin. Following the fusion, the cells are placed into a selection medium containing hypoxanthine, aminopterin, and thymidine (HAT medium) to grow *fused hybrid cell* lines selectively. The fused hybrid cells can survive in a HAT medium, because the cells combine the immortality of the myeloma cell with the genetic material of the spleen cell necessary for synthesis of HGPRT. The unfused myeloma cells are killed by the HAT medium because they do not have the HGPRT gene and the unfused spleen cells cannot be maintained in the culture. Colonies arising from the fused cells are then screened for antibody production, and cell lines secreting antibody of the desired specificity are cloned in subcultures. In this way, a single clonal line can be isolated that produces an antibody with a specificity for a single antigen epitope and having a single binding energy or affinity.

Because of the unique ability of a monoclonal antibody to react with a single epitope on a multivalent antigen, the majority of monoclonal antibodies will not cross link and precipitate macromolecular antigens. Consequently, monoclonal antibodies have not found broad applicability in traditional precipitin methods. A practical advantage of using monoclonal antibodies is that two different antibody specificities can be used in a single incubation step. A solid phase antibody specific for a unique epitope and another enzyme-labeled or radiolabeled antibody specific for a different epitope can be reacted with an antigen in a single step. This eliminates the two-step sequential addition of an antigen and labeled antibody to the solid phase and one incubation step and one washing step, which would be necessary when using polyclonal antibodies binding to both sites.

Phage display technology provides a new in vitro approach for producing antibodies (single chain Fv fragments, Fab fragments, and whole antibody molecules) that mimics the immune system but does not require B-cell immortalization.[15,92] V genes coding for the heavy and light chain variable domains of immunoglobulin isolated from lymphocytes are amplified by the polymerase chain reaction and ligated into a filamentous bacteriophage vector to form combinatorial libraries of V_H and V_L genes. Individual bacteriophages display copies of a specific antibody on their surface and the phage library can be screened for the antibody of a defined specificity using immobilized antigen ("panning"). Large libraries displaying antibodies formed from greater than 10^{12} different V_H and V_L combinations can be constructed; this provides a rich source of antibodies with binding constants of 10^8 to 10^9 L/mol. Soluble antibody from selected bacteriophages can be secreted from infected bacteria (e.g., *Escherichia coli*) in yields of greater than 500 mg/L.

ANTIGEN ANTIBODY BINDING

Binding Forces

The strength of the binding of an antigen to an antibody depends on several forces acting cooperatively. They include van der Waals-London dipole-dipole interaction, hydrophobic interaction, and ionic coulombic bonding.[43,76]

Van Der Waals-London Dipole-Dipole Interactions

Van der Waals-London binding is caused by the attraction between atoms when they are brought together in close proximity. These interactions are basically electrostatic in nature and are applicable to polarizable, noncharged molecules, whose structure allows the electron cloud around the molecule to be distorted by outside forces in such a way that a transient dipole is produced. Such polarization results in

the formation of an instantaneous dipole moment, which in turn induces a dipole moment in adjacent molecules. The induced dipole moment is oriented in an antiparallel fashion with respect to the original dipole moment such that a net attractive force is produced. These forces operate over short distances (4 to 6 nm) and are more significant for larger molecules. Because polarizability varies inversely with temperature, the attractive force is inversely proportional to the temperature.

Hydrophobic Interaction

Hydrophobic interactions result because the association of nonpolar groups is energetically favored in aqueous or other polar solutions. In proteins, hydrophobic interactions serve to bend and fold a molecule in a way that brings nonpolar R groups inside to the less polar interior; polar R groups are oriented outside toward the more polar aqueous environment. Thus hydrophobic bonding forms an interior, hydrophobic protein core, where most hydrophobic side chains can closely associate and weakly bind. Hydrophobic interaction enhances or stabilizes antigen antibody binding but is not necessarily a driving force in such binding.[78]

Coulombic Bonds

Coulombic bonding results from the attraction between charged groups on the antigen and antibody, primarily COO^- and NH_3^+. The attraction between the charged groups is greatest in a medium with a low dielectric constant caused by reduced interaction of the solvent or other solute (salts) with the macromolecular ions. In a medium of high dielectric constant (aqueous solutions containing added salt), a diffuse double layer of charged particles will tend to shield the attraction of the charged species in the reactive sites of the antigen and antibody. This inhibition under certain circumstances can considerably reduce the binding constant for many antigen antibody systems.

Considering these forces, one would predict that changing pH, temperature, and ionic strength of the reaction medium should influence the binding of antigen and antibody. However, given that the lower and upper limit of pH is 6 and 8 and the temperature between 25 °C and 35 °C, these variables have only minimal effect on the rate of association and immune complex formation.[60,80] In fact, extremes in pH (less than 4.0 and greater than 8.0) can cause inhibition of binding or dissociation of already formed antigen antibody complexes. Such extremes ultimately result in some degree of denaturation of the proteins involved. Thus only changes in ionic strength will produce a significant affect on the rate of binding of antigen and antibody. This concept is studied further in the following sections.

Reaction Mechanism

The binding of antigen to antibody is not static but is an equilibrium reaction that proceeds in three phases. The initial reaction (phase 1) of a multivalent antigen (Ag_n) and a bivalent antibody (Ab) occurs very rapidly in comparison with the subsequent growth of the complexes (phase 2) and is depicted by the following equation:

$$Ag_n + Ab \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ag_nAb \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Ag_aAb_b \qquad (1)$$

where $k_1 >>> k_2$, n is the number of epitopes per molecule, and a and b are the numbers of antigen and antibody molecules per complex. Phase 3 of the reaction involves the precipitation of the complex after a critical size is reached. The speed of these reactions depends on electrolyte concentration, pH, and temperature, and on antigen and antibody types and the binding affinity of the antibody. The concentration of NaCl is important, and in most cases normal saline (NaCl, 0.15 mol/L) is used. Higher concentrations of NaCl can lead to smaller amounts of precipitate; this is due not to increased solubility of the antigen antibody complex, but to an equilibrium shift causing a given amount of antigen to combine with smaller amounts of antibody. Decreasing the NaCl concentration can lead to increased precipitation of other proteins. Generally the presence of divalent cations has no effect on precipitation.

It is best to use dilute solutions for determining the influence of such factors as ionic species, ionic strength, pH, and concentration of soluble linear polymers, or for optical analytical methods. Use of dilute solutions slows the growth of the antigen antibody complexes, and a more stable and more homogeneous population of complexes results. Most of the discussions presented in subsequent sections are based on dilute systems and may not pertain to solutions in which reactants are present in much higher concentrations.

Factors Influencing Binding

Factors that influence the strength of binding between an antigen and antibody include the ion species, ionic strength, and polymers.

Ion Species and Ionic Strength Effects

Cationic salts produce an inhibition of the binding of antibody with a cationic hapten.[31] The order of inhibition by various cations is $Cs^+ > Rb^+ > NH_4^+ > K^+ > Na^+ > Li^+$. This order corresponds to the decreasing ionic radius and increasing radius of hydration. Presumably the lesser degree of hydration permits greater interaction of the salt with an anionic group located in the antibody-combining site. Similar results were found for anionic haptens and anionic salts. For example, the order of inhibition of binding for anionic salts is $CNS^- > NO^{-3} > I^- > Br^- > Cl^- > F^-$, which again is in the order of decreasing ionic radius and increasing radius of hydration. If the competition theory as suggested by these experiments is correct, one would expect the degree of inhibition to be a concentration-dependent phenomenon, and indeed the rate of formation of immune complexes is slower in normal saline (NaCl, 0.15 mol/L) than

the same reaction carried out in deionized water. Given the above observation, F^- should be the anion of choice for immunochemical reaction buffers. In fact, F^- does provide a modest improvement over Cl^-, but the advantage is so small that laboratories rarely substitute toxic fluoride ion for innocuous chloride ion in buffer solutions. A small but measurable difference in the initial rate of combination of antigen and antibody can be seen for phosphate as compared with tris buffer, presumably owing to the charge difference in the buffer molecules.[74] In general, the most notable differences in reaction rates for the various anionic species evaluated are seen at t less than 5 minutes. When the reactions are evaluated at longer times (i.e., t greater than 5 minutes), the difference in rate of antigen antibody complex formation is relatively small for different anionic species.[60]

Polymer Effect[54]

In general, the solubility of a protein in the presence of different linear polymers is inversely proportional to the molecular weight of the polymer (i.e., the higher the molecular weight of the polymer, the lower the solubility of the protein). For example, in the presence of Dextran 500, the solubility of α-crystalline < fibrinogen < γ-globulin < albumin <<< tyrosine.[53,54] Laurent thus proposed a steric exclusion mechanism to explain the effect of polymers on protein solubility.[54] Assuming a fixed total volume (V_T) of solvent being occupied by both polymer and protein and defining the volume occupied by polymer as V_E (excluded volume, i.e., volume not accessible to proteins) and the volume occupied by protein as V', then the relation

$$V_T = V' + V_E \quad (2)$$

implies that any increase in V_E caused by an increase in number or size of polymer molecules forces a decrease in V' and an effective increase in the concentration of protein molecules. Hence, as V_E is increased, the *effective* protein concentration is increased, the probability of collision and self-association of protein molecules is increased, and large insoluble aggregates are formed.

Studies by Hellsing[35,36] have provided support for the steric exclusion model and have demonstrated that (1) the *composition* of the immune complex formed is not affected by the presence of a polymer; (2) there is no complex formed between the polymer and the antigen, antibody, or immune complex; (3) the polymer effect is dependent on the molecular weight of both antigen and polymer; (4) and the use of polymer in a reaction mixture can increase the precipitation of immune complex with low-avidity antibody. Addition of polymer to a mixture of antigen and antibody causes a notable increase in the rate of immune complex growth, especially during the early phase of the reaction.[74]

Numerous polymer species have been tested (Box 9-1) for applications in immunochemical methods. The most desirable characteristics of the polymer are high molecular weight, a high degree of linearity (minimal branching), and high aqueous solubility. Most investigators have found PEG 6000 in concentrations of 3 to 5 g/dL to be most useful.

Types of Reactions

Types of antigen antibody reactions that are of analytical importance are the precipitin reaction and those at a solid-liquid interface.

The Precipitin Reaction

If the number of antibody-combining sites is notably greater than the antigen-binding sites, ([Ab] >>> [Ag]), then antigen-binding sites are quickly saturated by antibodies before cross-linking can occur, and the formation of small antigen antibody complexes of the composition AgAb results (Figure 9-2, *A*). When an antibody is in moderate excess (i.e., [Ab] greater than [Ag]), the probability of cross-linking of Ag by Ab is more likely and hence large complex formation is favored (see Figure 9-2, *B*). When [Ag] is in great excess, large complexes would be less probable, and the theoretical minimum size of complexes would be Ag_2Ab (see Figure 9-2, *C*). This model describes the results observed when antigens and antibodies are mixed in various concentration ratios. The curve shown in Figure 9-3 is a schematic diagram of the classical precipitin curve. Although the concentration of total antibody is constant, the concentration of free antibody $[Ab]_f$ (i.e., not bound to antigen) and free antigen $[Ag]_f$ varies throughout the range for any given Ag/Ab ratio. A low Ag/Ab ratio exists in *A* of Figure 9-3 (zone of antibody excess). Under these conditions, $[Ab]_f$ exists in solution but $[Ag]_f$ does not. As total antigen increases, the size of the immune complexes increases up to equivalence (see *B*, Figure 9-3) where little or no $[Ab]_f$ or $[Ag]_f$ exists. This is the zone of maximum immune complex size. This equivalence zone does not represent a ratio of exact molar equivalence of reactants but is the optimal combining ratio for cross-linking in the particular system under evaluation. As Ag/Ab increases (see *C*, Figure 9-3), the immune complex size will decrease and $[Ag]_f$ will increase (zone of antigen excess). No $[Ab]_f$ should exist in this area of the curve. However, for a given Ag/Ab ratio, the population of immune complexes formed at equilibrium will be heterogeneous with respect to size and composition.

Reactions at a Solid-Liquid Interface

If the antigen or antibody of interest is bound to a solid phase, such as a cell membrane, or to a synthetic particle (polystyrene or cellulose), the protein will exist in a microenvironment that is different from that of a protein in free solution. The water surrounding the protein is more highly ordered near the surface of the solid phase, and a condition results that is more favorable for van der Waals-London dipole-dipole interaction and coulombic bonding. This situation favors the formation of low- and high-avidity antigen antibody complexes and, hence, can provide lower detection limits for analytical applications. Some studies

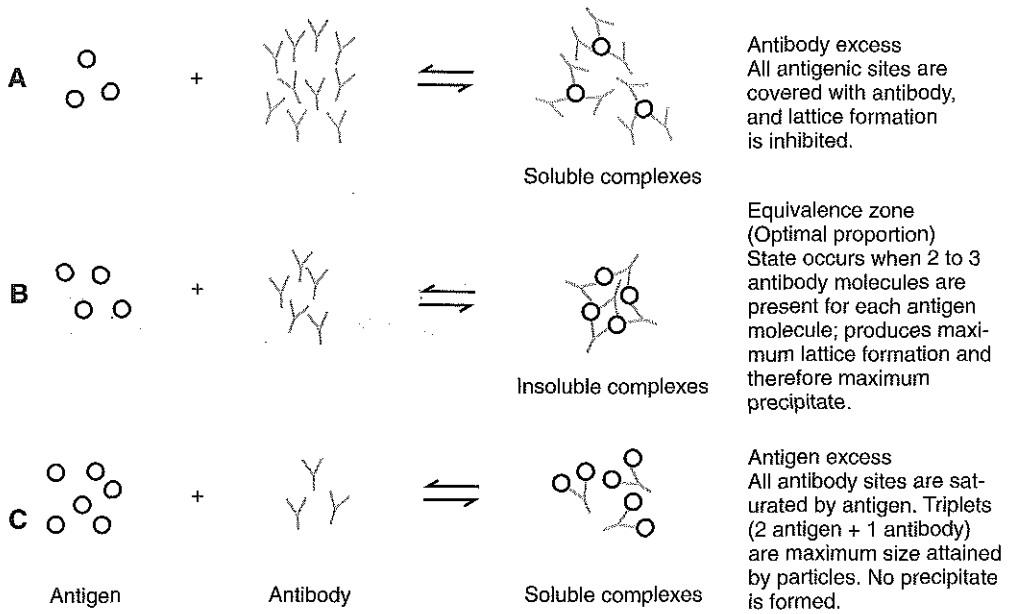

Figure 9-2 Schematic diagram for precipitin reaction.

have shown radiometric solid phase assays to be more sensitive than their counterpart solution assays. In one study using the same antibody pool of antihuman α_1-antitrypsin, the lower limit of detection for the solution method was 20 to 30 ng/mL; for the solid phase method, it was 5 to 10 ng/mL. The difference in the lower limit of detection is most likely a result of additional low-avidity antibody binding during the initial incubation in the solid phase system that does not occur as readily in the liquid phase.

Because of the exquisite specificity and the high affinity of antibodies for specific antigens, thousands of immunoassays have been developed to detect and measure a wide variety of biological analytes. In the next two sections, both qualitative and quantitative immunotechniques are discussed.

QUALITATIVE METHODS

Various types of immunotechniques have been used for qualitative purposes and include passive gel diffusion, immunoelectrophoresis (IEP), and Western and dot blotting.

PASSIVE GEL DIFFUSION

Many qualitative and quantitative immunochemical methods are performed in a semisolid medium, such as agar or agarose. The primary advantage in using a gelatinous medium is to stabilize the diffusion process with regard to mixing caused by vibration or convection and to allow visualization of precipitin bands for qualitative and quantitative evaluation of the reaction. Antigen antibody ratio, salt concentration, and polymer enhancement have the same influence on the antigen antibody reaction in gels as they have on reactions in solution.

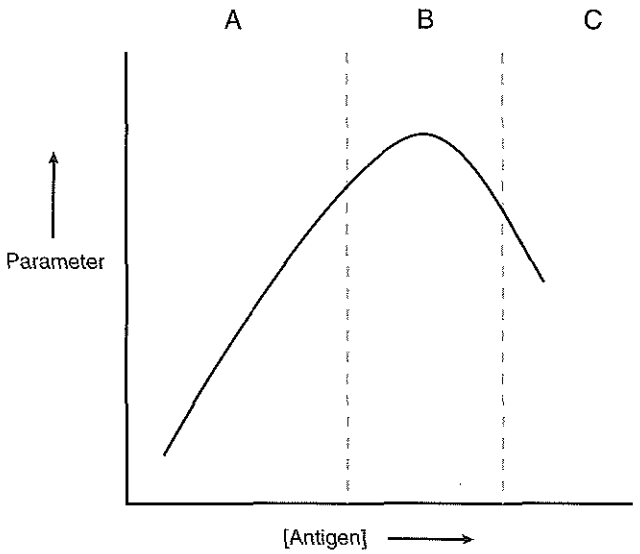

Figure 9-3 Schematic diagram of precipitin curve illustrating zones of antibody excess **(A)**, equivalence **(B)**, and antigen excess **(C)**. The parameter measured may be quantity of protein precipitated, light scattering, or another measurable parameter. Antibody concentration is held constant in this example.

BOX 9-1 Linear Polymers Used to Enhance Antigen Antibody Reaction

Polyethylene glycol (Carbowax)	Polyvinyl alcohol
Polypropylene glycol	Modified cellulose
Dextran	Polyvinyl pyrrolidone

If the matrix does not interact with the molecular species under investigation, passive diffusion of reactants in a semisolid matrix can be described by Fick's equation:

$$\frac{dQ}{dt} = -DA\frac{dC}{dx} \quad (3)$$

where dQ is the amount of diffusing substance that at time t passes through the area A; dC/dx is the concentration gradient; and D is the diffusion coefficient. The diffusion coefficient, D, is a directly proportional function of temperature; it is also a function inversely proportional to hydrated molecular volume of the diffusing species. The amount of diffusing species transferred from the origin to a distant point (over the migration distance) is dependent on the length of time diffusion is allowed to occur.

The initial concentration of antigen and antibody is critical. Each molecule in the system will achieve a unique concentration gradient with time. When the leading fronts of antigen and antibody diffusion overlap, the reaction will begin, but formation of a precipitin line will not occur until moderate antibody excess is achieved. A precipitin band may form and be dissolved many times by incoming antigen before equilibrium is established, and the position of the precipitin band becomes stable. Because heavier molecules diffuse more slowly, the position of the precipitin band is in part a function of the molecular masses of both antigen and antibody. The precipitin band acts as a specific barrier; neither specific antigen nor antibody can penetrate without being precipitated by the other, but unrelated molecules can cross the band of precipitation freely. However, if both antigen and antibody concentrations are too high, the excessive precipitate formed in the gel can physically block further diffusion of other molecules, including the antigen and antibody of interest, and cause anomalous results.

Basic approaches to passive diffusion include simple diffusion and double diffusion. With simple diffusion, a concentration gradient is established for only a single reactant. *Single immunodiffusion* usually depends on diffusion of an antigen into agar impregnated with antibody. A quantitative technique based on this principle is radial immunodiffusion (RID), which is discussed later. The second approach is double diffusion, in which a concentration gradient is established for both reactants (antigen and antibody).

Double immunodiffusion in two dimensions is a widely used immunotechnique and is known as the Ouchterlony method. It allows direct comparison of two or more test materials and provides a simple and direct method for determining whether the antigens in the test specimens are identical, cross reactive, or nonidentical.

The simplest method uses a standard Petri dish filled with agar in saline (2 to 4 g/dL) to a depth of about 3 mm. Holes are cut in the agar plate with a punch or a sharp cork borer. The plugs of agar are removed by suction, and the bottom of each well is sealed with a drop of agar in saline (1 g/dL) to prevent diffusion under the agar. When the same antigen is in both wells, the lines of precipitation fuse and are continuous—the reaction of identity (Figure 9-4, *A*). When the precipitin bands cross each other, it is a reaction of nonidentity (see Figure 9-4, *B*); if the two antigens are related but not identical, a reaction of partial identity is observed (see Figure 9-4, *C*). Here the cardinal point is that the precipitate serves as a barrier that does not block unrelated diffusing reactants. As shown in Figure 9-4, *D*, when two related antigens, Ag and Ag_1, are in separate wells and the respective antibodies, Ab and Ab_1, are in the third well, an AgAb precipitate forms on one side and blocks further diffusion of Ab from the antibody well. However, on the other side, the Ag_1Ab_1 precipitate does not stop Ab from migrating further and forming an AgAb spur.

Double diffusion can easily be done on a microscale using small glass slides. Only a small sample (1 μL) is required, and the reaction time is markedly decreased from as long as 1 week to 24 hours or less in some cases. Sharp lines are produced because the agar layer is thin, and the area from which the reactants diffuse is minute. Finally the slides can be stained or photographed unstained with an oblique light source illuminating the precipitant bands.

Note that a negative reaction does not necessarily imply absence of antibody or antigen. A negative reaction can result from using amounts of material too small for the detection limit of the method, or the antibody may be nonprecipitating.

Immunoelectrophoresis (IEP)

If several antigens of interest exist in a common solution (e.g., spinal fluid or serum), the various protein species can be separated and identified by IEP. This technique has been used extensively for the study of antigen mixtures, the evaluation of the specificity of antiserum, and the evaluation of human gammopathies.[44]

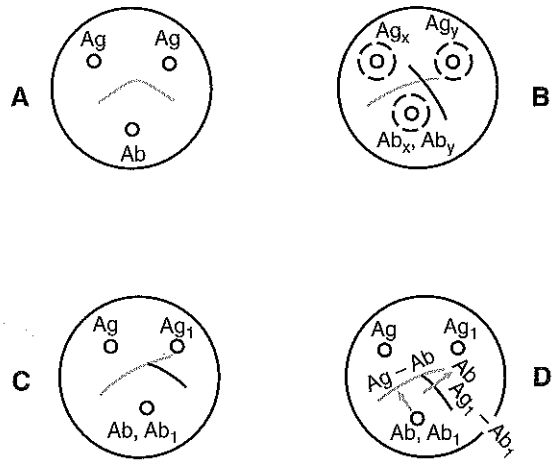

Figure 9-4 Double immunodiffusion in two dimensions by the Ouchterlony technique. **A,** Reaction of identity; **B,** reaction of nonidentity; **C,** reaction of partial identity; **D,** scheme for spur formation. *Ag,* Antigen; *Ab,* antibody.

The procedure is performed using an agarose gel medium poured onto a thin plastic sheet. The sample to be analyzed is placed in a reservoir in the gel, and an electrical field is applied across the gel surface. During electrophoresis, the proteins in the serum are separated according to their electrophoretic mobilities (Figure 9-5). Following electrophoresis, an antiserum against the protein of interest is placed in a trough parallel and adjacent to the electrophoresed sample. Simultaneous diffusion of the antigen from the separated sample and antibody from the trough results in formation of precipitin arcs, whose shape and position are characteristic of the individual separated proteins in the specimen. The pattern is interpreted after overnight development of the precipitate. By comparison with a known control separated on the same plate, tentative identification of individual proteins can be made. In some cases the characteristics of the precipitin arc, such as bowing, brushing at the end of the arc, or thickening, may suggest to the experienced observer the presence of special types of proteins.

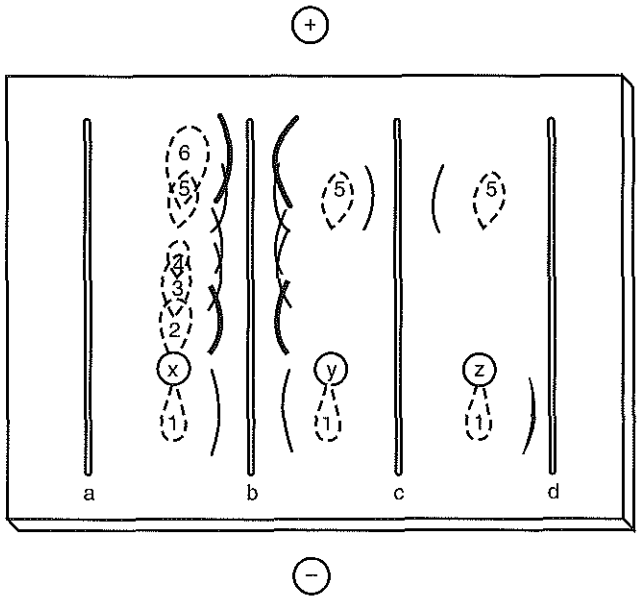

Figure 9-5 Configuration for immunoelectrophoresis. Sample wells are punched in the agar and/or agarose, sample is applied, and electrophoresis is carried out to separate the proteins in the sample. Antiserum is loaded into the troughs and the gel incubated in a moist chamber at 4 °C for 24 to 72 hours. Track *x* represents the shape of the protein zones after electrophoresis; tracks *y* and *z* show the reaction of proteins 5 and 1 with their specific antisera in troughs *C* and *D*. Antiserum against protein 1-6 is present in trough *B*.

In clinical laboratory medicine, this procedure has been applied to the evaluation of human myeloma proteins. However, the method is being replaced by immunofixation (IF) electrophoresis, particularly for the study of protein antigens and their split products, and for evaluation of human myeloma proteins (see later discussion of IF electrophoresis).

Crossed Immunoelectrophoresis (CRIE)

This technique, also known as two-dimensional IEP, is a variation of IEP wherein electrophoresis is also used in the second dimension to drive the antigen into a gel containing antibodies specific for the antigens of interest (Figure 9-6).[19,51] This technique is more sensitive and produces higher resolution than is possible with IEP. As with IEP, the specimen is applied to a cylindrical well cut in an agar medium and is then subjected to electrophoresis in the first dimension, followed by electrophoresis at a 90° angle to the first run through the gel that contains antibodies. Precipitin bands form at the zones of equivalence for each antigen. Precipitation occurs along lateral margins as the antigen advances and results in precipitation "peaks" for each antigen. An example of the application of CRIE is shown in Figure 9-7. A serum specimen treated with two different quantities of trypsin was evaluated for changes in α_1-antitrypsin. Formation of trypsin-antitrypsin complexes results in a second smaller peak cathodal to the native species. The resolution of the peaks in the second dimension may be improved by the use of a linear application of the sample into a rectangular slot instead of a well in the agar. Such application causes the proteins to move from the origin

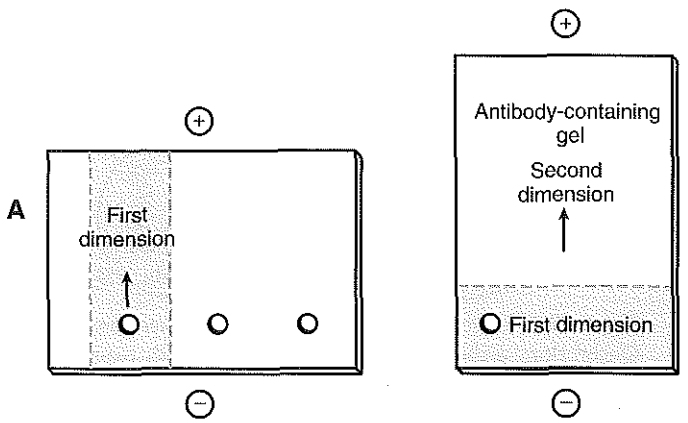

Figure 9-6 Two-dimensional (CRIE) electrophoresis. Diagram **(A)** shows the configuration for the first dimension of CRIE. The segment of the gel denoted by the *dashed lines* in diagram **(A)** is cut out and placed on a second plate. An upper gel containing antibody is added as shown in diagram **(B)**. Electrophoresis is now carried out at 90° relative to the first dimension run.

in relatively narrow bands and not in teardrop-shaped zones. Quantities of individual antigens can be estimated by measuring the peak area of the antigen under the precipitin arc and comparing it with the peak area of a standard antigen preparation.

Counterimmunoelectrophoresis (CIE)

With CIE, two parallel lines of wells are punched in the agar. One row is filled with antigen solution, and the opposing row is filled with antibody solution (Figure 9-8). If the solutions were allowed to passively diffuse over the next 18 to 24 hours, a precipitin line would form between the opposing wells where the antigen reacted with a specific antibody. With CIE, this process is made to occur more rapidly by applying a voltage across the gel so that the antigen and antibody move toward each other at a faster rate. The antigen migrates toward the anode; the antibody moves in the opposite direction as a result of electrophoresis, and a precipitin line is formed where they meet. Qualitative information (i.e., identification of antigen) is provided within 1 to 2 hours. This method has found application in the detection of bacterial antigens in blood, urine, and cerebrospinal fluid.

Immunofixation (IF)

This technique has gained widespread acceptance as an immunochemical method for identifying proteins.[3] As in IEP and CRIE, a first-dimension electrophoresis is performed in agarose gel to separate the proteins in the mixture. Subsequently, antiserum spread directly on the gel causes the protein(s) of interest to precipitate. The immune precipitate is trapped within the gel matrix, and all other nonprecipitated proteins can be removed by washing the gel. The gel may then be stained for identification of the proteins. CRIE is more sensitive than IF in terms of detection limit and also shows better resolution. For instance proteins of closely related or identical electrophoretic mobility can be distinguished better by CRIE, because in IF they will appear as a single band. In practice, IF is technically more efficient than either IEP or CRIE, and it produces patterns that are more easily interpreted. The utility of IF, which is now widely used for the evaluation of myeloma proteins, is illustrated in Figure 9-9.

Western Blotting

The techniques discussed above use a direct evaluation of the immunoprecipitation of the protein(s) in the gel. However, certain media, such as polyacrylamide, do not lend themselves to direct immunoprecipitation, nor is there always sufficient antigen concentration to produce an immunoprecipitate that will be retained in the gel during subsequent processing. Under these circumstances, a technique termed *Western blotting* can be used.[11,26] This technique involves an electrophoresis step followed by transfer of the separated proteins onto an overlying strip of nitrocellulose or a nylon membrane by a process called "electroblotting." Once the proteins are fixed to the membrane they can be detected

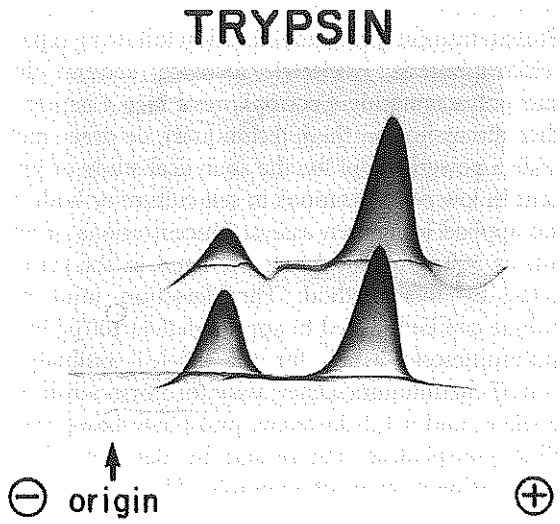

Figure 9-7 A CRIE pattern obtained with two different concentrations of trypsin added to normal serum. The first dimension was carried out from left to right and the second dimension from bottom to top. Two separate gels are shown, with the highest trypsin concentration at the bottom. Antibody against α_1-antitrypsin was present in the second dimension gel. The resulting pattern shows two distinct α_1-antitrypsin species, the free protease inhibitor *(right)* and protease-antiprotease complex *(left)*. This example illustrates the ability of CRIE to evaluate changes in specific protein structure.

using antibodies labeled with probes, such as radioactive isotopes or enzymes. By using such probes, the limits of detection can be 10 to 100 times lower than by using direct immunoprecipitation and staining of proteins. This technique is analogous to *Southern blotting* (electrophoresed DNA blotted onto a membrane), and *Northern blotting* (electrophoresed RNA blotted onto a membrane).

An example of this technique applied to the detection of human immunodeficiency virus type 1 (HIV-1) antibodies is shown in Figure 9-10. HIV-1 antigens are separated according to molecular weight by gel electrophoresis and then transferred to a nitrocellulose membrane by electroblotting. A serum sample is then incubated with a strip of the membrane. HIV-1 antibodies in the sample bind to the viral antigens transferred to the strip as discrete bands. After washing, the strip is incubated with an alkaline phosphatase antihuman immunoglobulin conjugate, which forms a complex with bound HIV-1 antibody. After a further washing step, the nitrocellulose strip is incubated with an alkaline phosphatase substrate solution (5-bromo-4-chloro-3-indolyl phosphate and nitroblue tetrazolium) to reveal bound conjugate as purple bands (where HIV-1 antibody is bound to specific viral antigen fixed in the membrane).

Protein transfer and immobilization following separation by electrophoresis, isoelectric focusing, sodium dodecyl sulfate polyacrylamide electrophoresis (see Chapter 5 for further discussion on these techniques), or other methods provide a powerful tool for the analytical study of proteins present in low concentrations in cell culture or body fluids. When applied to antigen assays, concentrations of antigen as low as 500 ng/mL or 2.5 ng per band in the gel can be detected by this method. The detection limit of the technique can be lowered to approximately 100 pg by using chemiluminescent assays for the labeled antibody (e.g., enhanced chemiluminescence assay for horseradish peroxidase labels, and a 1,2-dioxetane phosphate-based assay for alkaline phosphatase labels) and by detecting the light emission using x-ray or photographic film.[10,48,82]

Dot Blotting

A similar technique that bypasses the electrophoretic separation step is known as *dot blotting*. A protein sample to be analyzed is applied to a membrane surface as a small "dot" and dried. The membrane is then exposed to a labeled antibody specific for the test antigen contained in the dotted protein mixture. After washing, bound labeled antibody is detected with a photometric or chemiluminescent detection system.

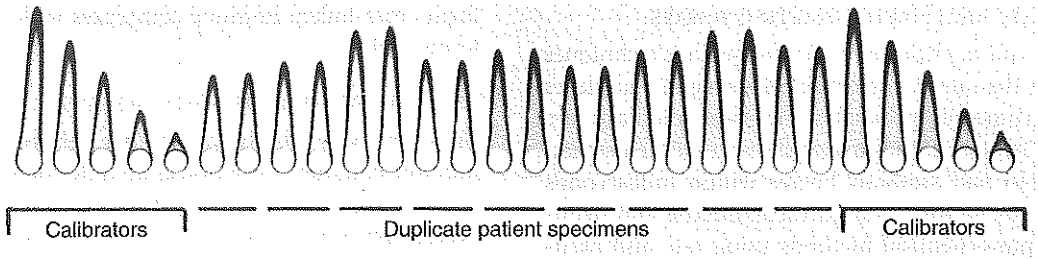

Figure 9-11 Rocket immunoelectrophoresis of human serum albumin. Patient samples were applied in duplicate. Standards were placed at opposite ends of the plate.

QUANTITATIVE METHODS

A number of immunochemical techniques have been used to quantify analytes of clinical interest. They include radial diffusion (RID) and electroimmunoassays, turbidimetric and nephelometric assays, and labeled immunochemical assays.

RADIAL IMMUNODIFFUSION AND ELECTROIMMUNOASSAY

Typically the two most commonly encountered gel-based methods for quantitative immunochemical studies are RID immunoassay and electroimmunoassay ("rocket" technique).

Radial Immunodiffusion Immunoassay

With this technique, a concentration gradient is established for a single reactant, usually the antigen. The antibody is uniformly dispersed in the gel matrix. Antigen is allowed to passively diffuse from a well into the gel until antibody excess exists and immune precipitation occurs; the antigen antibody interaction is manifested by a defined ring of precipitation around the antigen well. The ring diameter will continue to increase until equilibrium is reached. Calibrators are run at the same time as the sample, and a calibration curve of ring area or diameter versus concentration is plotted. The original procedure described by Mancini[59] requires the establishment of equilibrium before measurement of the precipitin ring diameter. Under equilibrium conditions, a linear relationship exists between antigen concentration and the square of the precipitin ring diameter. In addition, the precision of the measurement of the ring diameter is better than if the rings are measured before equilibrium is established. However, quantitative data can also be derived by reading the ring diameter before equilibrium is established.[23] This approach, although less precise, is often more practical for a clinical laboratory if available time for testing is at a premium.

Fick's equation predicts that the rate of diffusion is dependent on antigen size, molecular weight, and concentration. Whereas this is indeed the case for the *rate* of diffusion, the ultimate area of the precipitin ring at equilibrium is independent of these factors and dependent instead on the antigen antibody concentration ratio.[59] Antigen concentrations are calculated in both the preequilibrium and Mancini RID methods[23,59] by plotting the square of the precipitin ring diameter against calibrating antigen concentrations and by interpolating unknowns from this curve. RID can be made more sensitive using PEG to enhance precipitin line formation or by using ^{125}I- or enzyme-labeled reagents.[34,63,71]

Electroimmunoassay

In *electroimmunoassay,* as in RID, a single concentration gradient is established for the antigen, but in this case, an applied voltage is used to drive the antigen from the application well into a homogeneous suspension of antibody in the gel (Figure 9-11).[52] Unlike RID this produces a unidirectional migration of antigen and results in a lower limit of detection for electroimmunoassay methods. The height of the resulting rocket-shaped precipitin line is proportional to the antigen concentration. Quantitation is affected by using calibrators on the same plate along with the unknowns and then estimating the concentrations of unknowns from the heights of the "rockets" obtained. The calibration curve is linear only over a narrow concentration range, so samples may have to be diluted or concentrated as necessary. Electroimmunoassay methods produce the best results with antigens having a strong anodic mobility and intermediate to low molecular weight. Proteins, such as transferrin, C3, or IgG, with low anodal mobility or virtually no net charge at pH 8.6 (the most common pH used for the method) can be modified by carbamoylation or run at a lower pH to make their measurements by electroimmunoassay feasible. One advantage of electroimmunoassay is that more than one antigen can be measured simultaneously if appropriate conditions are chosen. The simultaneous use of more than one antiserum results in superimposed rockets that can be measured separately. Other modifications, such as the use of an intermediate gel that causes precipitation of C3, allow measurement of C3d in human serum and illustrate the exceptional versatility of this method.[9]

In many clinical laboratories, gel-based methods are restricted to qualitative studies. Quantitative data are more commonly obtained by turbidimetric and nephelometric methods, radioimmunoassays, enzyme immunoassays (EIAs), and fluorometric immunoassays.

Turbidimetric and Nephelometric Assays

Turbidimetry and nephelometry are convenient techniques for measuring the rate of formation of immune complexes in vitro. Instrumental principles for these methods are described in Chapter 3. Studies have shown that the reaction between antigen and antibody begins within milliseconds and continues for hours.[31,74] Both turbidimetric and nephelometric immunochemical methods using rate and pseudoequilibrium protocols have been described for proteins, antigens, and haptens. In rate assays, measurements are usually made within the first few minutes of the reaction, because the largest change *(dIs/dt)* in intensity of scattered light *(Is)* with respect to time is obtained during this time interval. For so-called equilibrium assays, it is necessary to wait 30 to 60 minutes so that the *dIs/dt* is small relative to the time required to make the necessary measurements. For the purpose of this discussion, such conditions are referred to as pseudoequilibrium because true equilibrium is not reached within the time allowed for these assays. Measurement of the *rate* of immune complex formation can also be used for quantitative immunochemical studies. Either *dIs/dt* or the time required to reach peak rate can be related to antigen concentration in a manner analogous to any other rate methodology. Rate nephelometric assays have the advantage that blank correction is not required, and that several samples can be assayed in a few minutes instead of the 30 to 60 minutes required for pseudoequilibrium methods.[6,14,38]

The analytical performance of nephelometric or turbidimetric assays can be significantly improved by increasing the reaction rate by addition of water-soluble linear polymers. This allows the use of much lower reactant concentrations and results in a more stable immune complex suspension.[13]

Nephelometric methods in general are more sensitive than turbidimetric assays and have an average lower limit of detection of 0.1 to 10 mg/L for a serum protein. Lower detection limits are obtained in fluids, such as cerebrospinal fluid and urine, because of their lower lipid and protein concentrations, which results in a better signal-to-noise ratio. In addition, for low molecular weight proteins (e.g., myoglobin, MW 17,800), assay detection limits can be lowered using a latex-enhanced procedure based on antibody-coated latex beads.[29]

Nephelometric and turbidimetric assays have also been applied to the measurement of drugs (haptens) using *inhibition techniques*. The reagent is made by attaching the drug of interest to a carrier molecule, such as bovine serum albumin. The hapten-bound albumin then competes with free hapten (drug introduced in sample) for the antihapten antibody. In the presence of free hapten, immune complex formation is decreased, because more antibody sites are saturated; thus light scattering is decreased. The decrease of light scattering is related to the concentration of free hapten. Both kinetic and pseudoequilibrium methods have been described.[17,25] In the absence of free hapten, bound hapten albumin reacts with available antihapten antibody sites to form cross-linked immune complexes with high light-scattering ability.

Labeled Immunochemical Assays

The previously discussed methods rely on evaluating the immune complex formation as an index of antigen antibody reaction. As demonstrated previously in equation (1), the overall reaction occurs in sequential phases, and only the final phase is the formation of the immune complex. However, the initial binding of the antibody and antigen has also been demonstrated to be very useful analytically and has been used with labeled antigens and antibodies to develop many sensitive and specific immunochemical assays. The reaction describing this initial binding and the kinetic constant for the overall reaction are shown in equations (4a) and (4b), respectively:

$$\mathrm{Ab} + \mathrm{Ag} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{AbAg} \tag{4a}$$

$$K = \frac{[\mathrm{AbAg}]}{[\mathrm{Ab}][\mathrm{Ag}]} \tag{4b}$$

where

k_1 = the rate constant for the forward reaction
k_{-1} = the rate constant for the reverse reaction
K = the equilibrium constant for the overall reaction

As would be predicted from the law of mass action, the concentration of Ab, Ag, and AbAg will be dependent on the magnitude of k_1 and k_{-1}. For polyclonal antiserum, the average avidity of the antibody populations will determine K (typically 10^8 to 10^{10} L/mol), and the magnitude of k_1 in comparison with k_{-1} will determine the ultimate limit of detection attainable with a given antibody population.

The original assays used radioactive labels, but concerns about the safe handling and disposal of radioactive reagents and waste have led to the development of alternative nonisotopic labels (Table 9-1).[47,66] In this section, the methodological principles on which these assays are based and the factors that affect their analytical sensitivity are discussed. In addition, specific examples of these assays and the types of labels that are used in them are evaluated. Commercial versions and applications of these assays are discussed in other chapters (see Chapters 3 and 11).

Methodological Principles

To exploit analytically the exquisite specificity and enhanced sensitivity that are possible with immunochemical assays, various methodological principles have been applied in their development. These include competitive and noncompetitive reaction formats and different processing schemes for performing the assays.

Competitive Versus Noncompetitive Reaction Formats

The two major types of reaction formats that are used in immunochemical assays (Figure 9-12) are termed *competi-*

TABLE 9-1 Labels Used for Nonisotopic Immunoassay

Chemiluminescent	Acridinium ester, sulfonyl acridinium ester, isoluminol
Cofactor	Adenosine triphosphate, flavin adenine dinucleotide
Enzyme	Alkaline phosphatase, marine bacterial luciferase, β-galactosidase, firefly luciferase, glucose oxidase, glucose-6-phosphate dehydrogenase, horseradish peroxidase, lysozyme, malate dehydrogenase, microperoxidase, urease, xanthine oxidase
Fluorophore	Europium chelate, fluorescein, phycoerythrin, terbium chelate
Free radical	Nitroxide
Inhibitor	Methotrexate
Metal	Gold sol, selenium sol, silver sol
Particle	Bacteriophage, erythrocyte, latex bead, liposome, quantum dot
Phosphor	Up-converting lanthanide-containing nanoparticle
Polynucleotide	DNA
Substrate	Galactosyl-umbelliferone

tive (limited reagent assays) and *noncompetitive* (excess reagent, two-site, or sandwich assays).

Competitive Immunoassays. In a *competitive* immunochemical assay, all reactants are mixed together either *simultaneously* or *sequentially.* In the simultaneous approach, the labeled antigen (Ag*) and unlabeled antigen (Ag) compete for binding to the antibody. In such a system, the avidity of the antibody for both the labeled and unlabeled antigen must be the same. Under these conditions, the probability of

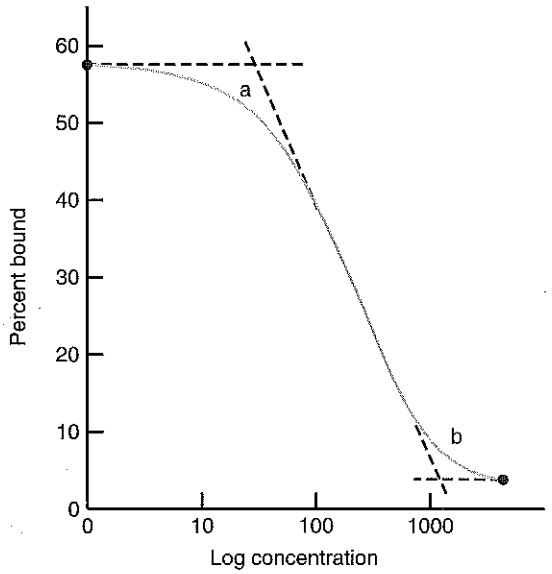

Figure 9-13 A schematic diagram of the dose-response curve for a typical immunoassay. The analytically useful portion of the curve is bracketed by points *a* and *b*.

the antibody binding the labeled antigen is inversely proportional to the concentration of unlabeled antigen; hence, bound label is inversely proportional to unlabeled antigen concentration.

In a *sequential* competitive assay, unlabeled antigen is first mixed with excess antibody, and binding is allowed to reach equilibrium (see Figure 9-12, step 1). Labeled antigen is then sequentially added (step 2) and allowed to equilibrate. After separation the bound label is determined and used to calculate the unlabeled antigen concentration. Using this two-step method, a larger fraction of the unlabeled antigen can be bound by the antibody than in the simultaneous assay, especially at low antigen concentrations. Consequently, this strategy can provide a twofold to fourfold improvement in the detection limit of a sequential immunoassay compared with that of a simultaneous assay, provided $k_1 >> k_{-1}$. This improvement in detection limit results from an increase in AgAb binding (and thus in a decrease in Ag* binding), which is favored by the sequential addition of Ag and Ag*. If $k_1 >> k_{-1}$, dissociation of AgAb becomes more likely, resulting in an increased competition between Ag* and Ag. A typical immunochemical binding curve is shown in Figure 9-13.

Noncompetitive Immunoassays. In a typical *noncompetitive assay* for an antigen, a capture antibody is first passively adsorbed or covalently bound to the surface of a solid phase. Various sequences in which the capture antibody can be attached are shown in Box 9-2. The simplest involves direct attachment to the solid phase. However, this can lead to some loss of antibody binding capacity because of steric factors or attachment of the antibody via its Fab region. To protect the binding properties of the antibody, more complex sequences have been devised. For example, the solid support can be coated with an antispecies antibody, and then

the antispecies antibody can be used to immobilize the capture antibody via an antigen antibody reaction.

In the second stage of the assay, the antigen from the sample is allowed to react with the solid phase, capture antibody; other proteins are washed away; and a labeled antibody (conjugate) is added that reacts with the bound antigen through a second and distinct epitope. After washing again, the bound label is determined, and its concentration or activity is directly proportional to the concentration of antigen.

In noncompetitive assays, the capture and labeled antibody can be either polyclonal or monoclonal. If monoclonal antibodies having specificity for distinct epitopes are used, it is possible to incubate the sample and conjugate simultaneously with the capture antibody, thus simplifying the assay protocol.

Noncompetitive immunoassays can be performed in either a simultaneous or sequential mode. However, in the simultaneous mode, a situation can occur in which a high concentration of analyte can saturate both the capture and labeled antibodies. When this occurs, the calibration curve of the assay exhibits a "hook effect" in which the assay response drops off at high analyte concentrations. Under these conditions, the analyte is present in such high concentrations that it reacts simultaneously with the capture antibody and the labeled antibody. This reduces the number of complexes formed and produces a falsely low result. Assays for analytes for which the normal pathological concentration range is very wide (e.g., hCG, AFP) are particularly prone to this problem. Dilutions of a sample are usually reanalyzed to check for this type of analytical interference. The hook effect can be eliminated by adopting a sequential assay format[66] and by ensuring that the concentrations of capture and labeled antibody are sufficiently high to cover analyte concentrations over the entire analytical range of the assay.

Heterogeneous Versus Homogeneous Immunochemical Assays

Immunochemical assays that require a separation of the free from the bound label are termed *heterogeneous*; those that do not are called *homogeneous.*

BOX 9-3 Separation Methods Used in Immunoassays

Adsorption
Charcoal, Florisil, talc

Precipitation
Polymer precipitation: polyethylene glycol
Solvent or salt precipitation: ethanol, dioxane, $(NH_4)_2SO_4$
Protein A or double (second) antibody precipitation

Solid Phase Antibodies
Antibodies or other binding proteins (e.g., protein A, biotin-avidin, and biotin-streptavidin) adsorbed or covalently attached to an insoluble matrix (e.g., plastic beads, inside surface of a plastic tube or microwell, and magnetic beads)

Miscellaneous
Electrophoresis
Gel filtration
Ion exchange
Radial partition

Heterogeneous Assays. Heterogeneous assays implicitly assume that $k_1 >> k_{-1}$ and that a variety of physical separation techniques (Box 9-3) are used to separate the free-label (Ag*) from the bound-labeled antigen (Ag*Ab). The most widely used of these techniques are precipitation and liquid phase and solid phase adsorption.

Precipitation of the bound-labeled antigen (Ag*Ab) from the reaction mixture can be achieved chemically by the addition of a protein-precipitating chemical, such as $(NH_4)_2SO_4$, or immunologically by the addition of a second, "precipitating" antibody. In the latter approach, if the primary antibody was obtained from rabbit antiserum, the precipitating antibody would be contained in a goat or sheep antiserum raised against rabbit globulin. This approach has the advantage that it can be used for practically any assay; however, it has the disadvantage that it usually requires longer assay times and additional processing steps.

In liquid phase adsorption, the free antigen is adsorbed onto particles of activated charcoal or dextran-coated charcoal that are added directly to the reaction mixture. The particles of charcoal and the adsorbed antigen are then removed by allowing them to settle or by centrifugation. The disadvantage of this separation technique is that the time of contact between the adsorbent and the incubation mixture is critical, especially for the more active adsorbents, such as activated charcoal.

Solid phase adsorption is the separation technique that is currently the most popular and widely used in both manual and automated immunoassays (see Chapter 11). In this technique, the binding and competition of the labeled and unlabeled antigens for the binding sites of the antibody occur on the surface of a solid support onto which the capture anti-

†Personal communication.

body has been attached by either physical adsorption or covalent bonding. Several different types of solid support have been used, including the inner surface of plastic tubes or wells of microtiter plates and the outer surface of insoluble materials, such as cellulose or magnetic latex beads or particles. With the tubes and microtiter plates, the solid surface containing the attached antibody and bound antigen is washed "in place," and indicator reagents are subsequently added to complete the assay. When beads or particles are used, they are added directly to the reaction mixture and after incubation are removed by centrifugation or magnetic separation. After the supernatant is removed by siphoning or decanting, the beads or particles are washed and indicator reagents subsequently added to complete the assay.

Homogeneous Assays. The development of homogeneous assays that do not require a separation of the bound- and free-labeled antibody or antigen was a major advance in the field of immunochemical analysis. In this type of assay, the activity of the label attached to the antigen is directly modulated by antibody binding, with the magnitude of the modulation being proportional to the concentration of the antigen or antibody being measured. Consequently, in practice it is only necessary to incubate the sample containing the analyte antigen with the labeled antigen and antibody and then directly measure the activity of the label "in place," thus making these assays technically easier and faster. The original homogeneous immunoassay was developed for drug analysis and used a nitroxide spin label and was termed a free radical immunoassay technique.[56] The electron spin resonance spectrum of this label was modulated when the nitroxide-labeled drug was bound by a drug-specific antibody. This procedure was quickly superseded by homogeneous immunoassays that used enzyme labels and could be performed on spectrophotometric analyzers (see subsequent descriptions of enzyme multiplied immunoassay technique (EMIT) and cloned enzyme donor immunoassay [CEDIA]).[37,72]

Analytical Detection Limits

The analytical detection limits of competitive and noncompetitive immunoassays are determined principally by the affinity of the antibody and the detection limit of the label used, respectively.[21,40,41,69] Calculations have indicated that a lower limit of detection of 10 fmol/L (*i.e., 600,000 molecules* of analyte in a typical sample volume of 100 μL) is possible in a competitive assay using an antibody with an affinity of 10^{12} L/mol.* Table 9-2 illustrates the detection limits for isotopic and nonisotopic labels. A radioactive label, such as ^{125}I, has low specific activity (7.5 million labels necessary for detection of 1 disintegration/s) compared with enzyme labels and chemiluminescent and fluorescent labels. Enzyme labels provide an amplification (each enzyme label produces many detectable product molecules), and the detection limit for an enzyme can be improved by replacing the conventional photometric detection reaction by a chemiluminescent or bioluminescent reaction. The combination of amplification and an ultrasensitive detection reaction makes noncompetitive chemiluminescent EIAs among the most sensitive types of immunoassay. Fluorescent labels also have

*In 1989, Spencer introduced the term "functional sensitivity" and defined it as the lowest concentration of an analyte for which clinically useful results can be reported (Spencer CA. Thyroid profiling for the 1990s: free T4 estimate or sensitive TSH measurement. J Clin Immunoassay 1989; 12:82-9.) This term has become widely adopted and used as one of the measures of the analytical performance of an immunoassay.

high specific activity, and a single high-quantum yield fluorophor can produce 100 million photon/s. In practice, several factors degrade the detection limit of an immunoassay; these include background signal from the detector, assay reagents, and nonspecific binding of the labeled reagent.

Secondary labels, such as biotin, can also be used to introduce amplification into an immunoassay. The binding constant of the biotin-avidin complex is extremely high (10^{15} L/mol); capitalizing on this system allows immunoassay systems to be devised that are even more sensitive than the simple antibody systems. A biotin-avidin system uses a biotin-labeled first antibody. Biotin can be attached to the antibody in relatively high proportion without loss of immunoreactivity by the antibody.[5,32] When an avidin-conjugated label is added, a complex of Ag : Ab-biotin : avidin label is formed. Further amplification can be achieved by a biotin : avidin : biotin linkage, because the binding ratio of biotin : avidin is 4 : 1. If the label is an enzyme, then large numbers of enzyme molecules in the complete complex provide a large increase of enzymatic activity coupled with the small amount of antigen being determined, and the antigen assay is correspondingly more sensitive. Other strategies to lower the analytical detection limits of immunoassays include the use of streptavidin-thyroglobulin conjugates and macromolecular complexes of multiple-labeled thyroglobulin and streptavidin-thyroglobulin.[19] In these reagents, the thyroglobulin acts as a carrier for multiple labels (e.g., Eu^{3+}), and amplification factors of several thousand are achieved.

Examples of Labeled Immunoassays

In the decade following the pioneering developments of Yalow and Berson,[94] all immunoassays used a radioactive label in a competitive assay format. Since the introduction of enzyme immunochemical assays in the 1970s,[56,72] a vast array of sophisticated immunochemical assays have evolved and have been very widely applied. Specific examples of several of these assays follow; others are briefly described in Box 9-4.

Radioimmunoassay

Radioimmunoassays (RIAs) were developed in the 1960s and used radioactive isotopes of iodine (^{125}I, ^{131}I) and tritium (^{3}H) as labels.[20,94] Radiolabeling of antigen with an isotope can cause changes in reactivity with the antibody. Therefore labeled and unlabeled antigens always need to be evaluated when a competitive assay is used to ensure that the antibody reacts equally with each form. Labeled antibody assays (immunoradiometric assay) have the advantage of not requiring a quantity of purified antigen because the antigen does not have to be labeled. This also obviates potential problems that may be caused by iodination of labile antigens. Antibodies are more stable proteins and are less difficult to label without damaging the protein's function. Combinations of labels (e.g., ^{57}Co and ^{125}I) have been used for simultaneous assays of vitamin B_{12} and folate,[90] lutropin and follitropin, and thyrotropin and free thyroxine. Nonseparation RIAs have also been developed based on the modulation of a tritium label by particles loaded with scintillation molecules and on the modulation of a ^{125}I label by a tungsten particle[81] and have found application in drug discovery assays.

Enzyme Immunoassay

Enzyme immunoassays use the catalytic properties of enzymes to detect and quantify immunological reactions. In practice, enzyme-labeled antibodies or antigens (i.e., conjugates) are first allowed to react with ligands, and enzyme substrates are subsequently added. Measurement of the resultant decrease in substrate concentration or increase in product concentration is then used either to detect or quantitate the antigen antibody reaction. Alkaline phosphatase, horseradish peroxidase, glucose-6-phosphate dehydrogenase, and β-galactosidase enzyme labels predominate in EIA.[27,28] Enzyme-labeled antibody and antigen conjugates are prepared by covalent coupling procedures using bifunctional reagents (e.g., glutaraldehyde, N-succinimidyl 3-[pyridyl] propionate),[4] and recombinant conjugates have been prepared from fused genes and used in research EIAs (e.g., proinsulin-alkaline phosphatase).[58]

Various detection systems have been used to monitor and quantify EIAs. Assays that produce compounds that can be monitored photometrically are very popular, because compact, high-performance photometers are now available that are versatile, reliable, simple to operate, and relatively inexpensive. However, EIAs that use fluorescent- or chemiluminescent-labeled substrates or products are often preferred to photometry-based assays owing to the inherent sensitivity of fluorescent and chemiluminescent measurements (see Chapter 3 and Table 9-2). Immunoassays that incorporate horseradish peroxidase as a label can be assayed by a chemiluminescence using a mixture of luminol, peroxide, and an enhancer such as *p*-iodophenol[82] or by using an acridan derivative.[2] Umbelliferone phosphate is a nonfluorescent substrate that is converted to the highly fluorescent umbelliferone by alkaline phosphatase. This reaction is used to quantify the alkaline phosphatase label.[24] A very sensitive assay for alkaline phosphatase labels uses a chemiluminescent adamantyl 1,2-dioxetane aryl phosphate substrate.[10] The enzyme dephosphorylates the substrate, which decomposes with a concomitant long-lived glow of light (detection limit for alkaline phosphatase using this assay is 1 zeptomole [10^{-21} moles]). Enzyme cascade reactions have also been applied to the detection of enzyme labels in EIA; the principle of a cascade assay for alkaline phosphatase is illustrated in Figure 9-14. The advantage of such an assay is that it combines the amplification properties of two enzymes—the alkaline phosphatase label and the alcohol dehydrogenase in the assay reagent—thus producing a very sensitive assay (see Table 9-2).

BOX 9-4 Examples of Other Nonisotopic Immunoassays*

Bioluminescent Immunoassays[68]
Native or recombinant apoaequorin (from the bioluminescent jellyfish *Aequorea*) is used as the label. It is activated by reaction with coelenterazine, and light emission at 469 nm is triggered by reaction with calcium ions (calcium chloride).

Fluorescence Excitation Transfer Immunoassay[84]
Homogeneous competitive assay in which a fluorophore (donor)-labeled antigen competes with an antigen in the sample for binding sites on an antibody labeled with a fluorescent dye (acceptor). The fluorescence of the donor is quenched when it is bound to the acceptor-labeled antibody.

Immuno-PCR[73]
Heterogeneous immunoassay in which a piece of single- or double-stranded DNA is used as a label for an antibody in a sandwich assay. Bound DNA label is amplified using the polymerase chain reaction (PCR). The amplified DNA product is separated by gel electrophoresis and quantitated by densitometric scanning of an ethidium stained gel.

***Luminescent Oxygen Channeling Immunoassay* (LOCI)**[83]
Homogeneous sandwich immunoassay in which an antigen links an antibody-coated sensitizer dye-loaded particle (250-nm diameter) and an antibody-coated particle (250-nm diameter) loaded with a mixture of a precursor of a chemiluminescent compound and a fluorophore. Irradiation produces singlet oxygen at the surface of the sensitizer dye-loaded particle. This diffuses ("channels") to the other particle held in close proximity by the immunochemical reaction between the antigen and antibodies on the particles. The singlet oxygen reacts with the chemiluminescent compound precursor in the particle to form a chemiluminescent dioxane, which then decomposes to emit light via a fluorophore-sensitized mechanism. No signal is obtained from precursor fluorophore-loaded particles that are not linked via immunological reaction with an antigen.

Phosphor immunoassay[62,95]
Heterogeneous immunoassay in which an upconverting phosphor nanoparticle is used as a label. The nanoparticle (200- to 400-nm diameter) is a crystalline lanthanide oxysulfide. It absorbs two or more photons of infrared light (980 nm) and produces light emission at a shorter wavelength (antiStokes shift). The phosphorescence is not influenced by reaction conditions (e.g., temperature or buffer) and there is no up-converted signal from biological components in the sample (low background). Multiplexing is possible because different types of particle produce different wavelengths of phosphorescence (e.g., yttrium/erbium oxysulfides are green [550 nm] and yttrium/thulium oxysulfide particles are blue [475 nm]).

Quantum Dot Immunoassay[16,33,70]
Heterogeneous immunoassay in which a nanometer-sized (less than 10 nm) semiconductor quantum dot is used as a label. A quantum dot is a highly fluorescent nanocrystal composed of CdSe, CdS, ZnSe, InP, or InAs or a layer of ZnS or CdS on, for example, a CdSe core. Multiplexing is possible with these labels because the emission properties can be modulated by changing the size and composition of the nanocrystal (e.g., CdS emits blue light, InP emits red light).

Solid Phase, Light-Scattering Immunoassay[67]
Indium spheres are coated on glass to measure an antibody binding to an antigen. Binding of antibodies to antigens increases dielectric layer thickness, which produces a greater degree of scatter than in areas where only an antigen is bound. Quantitation is achieved by densitometry.

Surface Effect Immunoassay[77]
An antibody is immobilized on the surface of a waveguide (a quartz, glass, or plastic slide, or a gold- or silver-coated prism), and binding of an antigen is measured directly by total internal reflection fluorescence, surface plasmon resonance, or attenuated total reflection.

*Superscript numbers refer to the references found at the end of this chapter.

Types of enzyme-linked immunoassay include *enzyme-linked immunosorbent assay (ELISA), enzyme multiplied immunoassay technique (EMIT),* and *CEDIA.*

Enzyme-Linked Immunosorbent Assay. ELISA is a heterogeneous EIA technique that is widely used in clinical analyses.[22,86] In this type of assay, one of the reaction components is nonspecifically adsorbed or covalently bound to the surface of a solid phase, such as that of a microtiter well, a magnetic particle, or a plastic bead. This attachment facilitates separation of bound- and free-labeled reactants. In the most common approach to using the ELISA technique, an aliquot of sample or calibrator containing the antigen to be quantitated is added to and allowed to bind with a solid phase antibody. After washing, enzyme-labeled antibody is added and forms a "sandwich complex" of solid phase Ab-Ag-Ab-enzyme. Excess (unbound) antibody is then washed away, and enzyme substrate is added; the enzyme catalytically converts the substrate to product(s), the amount of which is proportional to the quantity of antigen in the sample. Antibodies in a sample can also be quantitated using an ELISA procedure in which antigen instead of antibody is bound to a solid phase, and the second reagent is an enzyme-labeled antibody specific for the analyte antibody. The procedure is otherwise identical to that described earlier for the measurement of antigens. For example, in a microtiter plate format, ELISA assays have been used extensively for detection of antibodies to viruses and parasites in serum or whole blood.[87] In addition, enzyme conjugates coupled

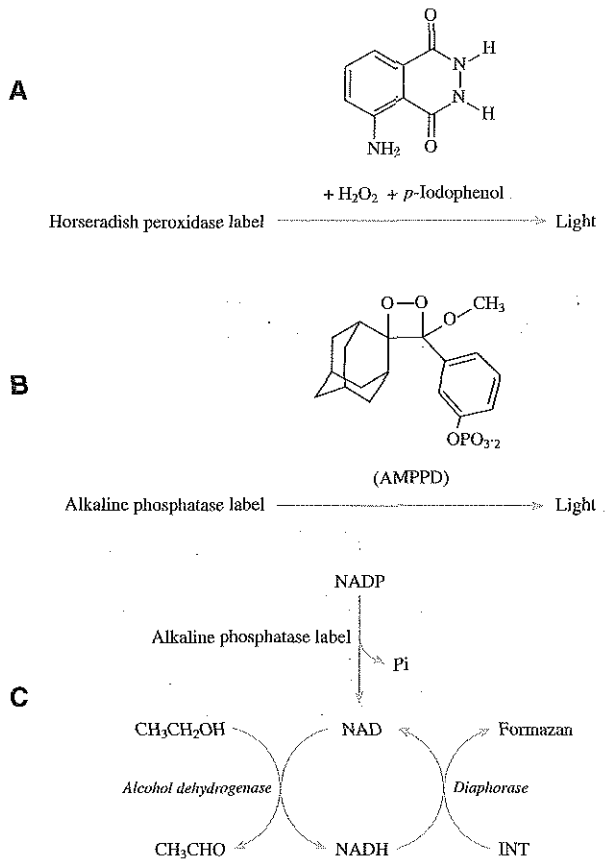

Figure 9-14 Ultrasensitive assays for horseradish peroxidase and alkaline phosphatase labels. **A,** Chemiluminescent assay for horseradish peroxidase label using luminol. **B,** Chemiluminescent assay for an alkaline phosphatase label using AMPPD. **C,** Photometric assay for an alkaline phosphatase label using a cascade detection reaction. *INT, p*-iodonitrotetrazolium violet.

with substrates that produce visible products have been used to develop ELISA type of assays with results that can be interpreted visually. Such assays have been found to be very useful in screening, point-of-care, and home testing applications.

Enzyme Multiplied Immunoassay Technique. EMIT is a homogeneous EIA that is also very widely used in clinical analyses, an illustration of which is shown in Figure 9-15. Because EMIT does not require a separation step, it is simple to perform and has been used to develop a wide variety of drug, hormone, and metabolite assays.[72] Because of their operational simplicity, EMIT type assays are easily automated and are included in the repertoire of many automated clinical and immunoassay analyzers (see Chapter 11). In this technique, antibody against the analyte drug, hormone, or metabolite is added together with substrate to the patient's sample. Binding of the antibody and analyte occurs. An aliquot of the enzyme conjugate of the analyte drug, hormone, or metabolite is then added as a second reagent; the enzyme-analyte conjugate then binds with the excess analyte antibody, forming an antigen antibody complex.

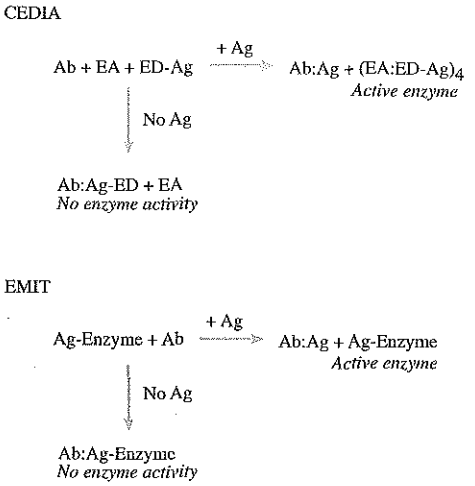

Figure 9-15 CEDIA and EMIT homogeneous immunoassays. *EA,* Enzyme acceptor; *ED,* enzyme donor.

This binding of the analyte antibody with the enzyme analyte conjugate affects enzyme activity by physically blocking access of the substrate to the active site of the enzyme or by changing the conformation of the enzyme molecule and thus altering its activity. To complete the assay, the resultant enzyme activity is measured. The relative change in enzyme activity resulting from the formation of the antigen antibody complex is proportional to the drug, hormone, or metabolite concentration in the patient's sample. Concentration of the analyte is calculated from a calibration curve prepared by analyzing calibrators that contain known quantities of the analyte in question.

Cloned Enzyme Donor Immunoassay. As shown in Figure 9-15, CEDIA is a second type of homogeneous EIA; this assay was the first EIA designed and developed using genetic engineering techniques.[37] Inactive fragments (the enzyme donor and acceptor) of β-galactosidase are prepared by manipulation of the Z gene of the *lac* operon of *E. coli.* These two fragments spontaneously reassemble to form active enzyme even if the enzyme donor is attached to an antigen. However, binding of antibody to the enzyme donor antigen conjugate inhibits reassembly, and no active enzyme is formed. Thus competition between antigen and the enzyme donor antigen conjugate for a fixed amount of antibody in the presence of the enzyme acceptor modulates the measured enzyme activity (high concentrations of antigen produce the least inhibition of enzyme activity; low concentrations produce the greatest inhibition).

Fluoroimmunoassay

Examples of fluorophores that are used as labels in *fluoroimmunoassay* and their properties are listed in Table 9-3.[93] Initially, background fluorescence from drugs, drug metabolites, and protein-bound substances, such as bilirubin, limited the utility of this technique. However, this problem has largely been overcome by the use of rare earth (lanthanide) chelates and background rejection (time-resolved)

TABLE 9-3 Properties of Fluorescent Labels

procedures (see Chapters 3 and 11).[18,19,75] Fluorescent emissions from lanthanide chelates (e.g., europium, terbium, and samarium) are long lived (greater than 1 μs) compared with the typical background fluorescence encountered in biological specimens. In a time-resolved fluoroimmunoassay, a europium chelate label is excited by a pulse of excitation light (0.5 μs), and the long-lived fluorescence emission from the label is measured after a delay (400 to 800 μs). By this time, any short-lived background signal has decayed.

Fluorescent polarization immunoassay is a type of homogeneous fluoroimmunoassay that is widely used to measure drugs and other analytes (Figure 9-16). The polarization of the fluorescence from a fluorescein-antigen conjugate is determined by its rate of rotation during the lifetime of the excited state in solution. A small, rapidly rotating fluorescein antigen conjugate has a low degree of polarization; however, binding to a large antibody molecule slows down the rate of rotation and increases the degree of polarization. Thus binding to antibody modulates polarization, and a homogeneous assay is possible.[42,57,65] Another type of nonseparation fluoroimmunoassay uses a multilayer device to eliminate the necessity for separation of bound and free fractions.[30] The device consists of two agarose layers separated by an opaque layer of iron oxide. A sample is added to the upper (10 μm) layer and diffuses through the iron oxide (10 μm) layer to the thin (1 μm) signal layer that contains antibody:antigen rhodamine complexes. Antigen rhodamine conjugate is displaced from the signal layer by antigen in the sample and diffuses into the upper layer. Residual bound antigen rhodamine conjugate in the signal layer is measured by front-surface fluorometry. Displaced free conjugate does not contribute to the signal, because it is shielded from the fluorescence excitation light by the iron oxide layer. As listed in Box 9-4, many other types of homogeneous fluoroimmunoassays have been described in the literature.[28,47,66,84]

Chemiluminescence Immunoassay

Chemiluminescence is the name given to light emission produced during a chemical reaction (see Chapter 3). Isoluminol and acridinium esters are important examples of chemiluminescent labels used in *chemiluminescent immunoassay.* Oxidation of isoluminol by hydrogen peroxide in the presence of a catalyst, such as microperoxidase, produces a relatively long-lived light emission at 425 nm, and oxidation of an acridinium ester by alkaline hydrogen peroxide in the presence of a detergent (e.g., Triton X-100) produces a rapid flash of light at 429 nm. Acridinium and sulfonyl acridinium esters are high specific activity labels (detection limit for the label is 800 zeptomoles) that can be used to label both antibodies and haptens (Figure 9-17).[1,50,89]

Electrochemiluminescence Immunoassay

Ruthenium (II) tris(bipyridyl) (Figure 9-17, *B*) undergoes an electrochemiluminescent reaction (620 nm) with tripropylamine at an electrode surface, and this chelate is now used as a label in competitive and sandwich *electrochemiluminescence immunoassays.* Using this label, various assays have been developed in a flow cell using magnetic beads as the solid phase. Beads are captured at the electrode surface, and an unbound label is washed out of the cell by a wash buffer. Label bound to the bead undergoes an electrochemiluminescent reaction, and the light emission is measured by an adjacent photomultiplier tube.[7,39]

Simplified Immunoassays

The integration of the technical advances made in molecular immunology with those made in the material and processing sciences has resulted in the development of a number of "simplified" immunoassays for use in physicians' offices or the home (i.e., the so-called point-of-care market). Early efforts were directed toward pregnancy and fertility testing and were based on agglutination and inhibition of agglutination using labeled red blood cells or latex particles in a slide format. Subsequently, sandwich immunoassays have been adapted for similar applications. For example, as listed in the package insert, the ICON II pregnancy test (Beckman Coulter, Fullerton, Calif.) is an operationally simple and sensitive assay for human chorionic gonadotropin (hCG) that detects hCG down to 10 mIU/mL for serum and 20 mIU/mL

for urine. As shown in Figure 9-18, the ICON II test is a sandwich EIA device that uses a murine monoclonal antibody, which is immobilized onto the surface of a microporous nylon membrane located on top of an adsorbent pad.[85] The pad functions as a capillary pump to draw liquid through the membrane. To perform an analysis, an aliquot of urine is added to the surface of the membrane; hCG is removed as liquid is drawn through it, resulting in the removal of hCG in the sample by its binding to the capture antibody on the membrane. Next, a matched murine monoclonal anti-hCG antibody alkaline phosphatase conjugate is added and allowed to drain into the adsorbent pad. Wash solution is then added, followed by an indoxyl phosphate substrate. Bound conjugate converts this to an insoluble indigo dye, which appears as a discrete blue spot. The second generation of the ICON test includes two additional control zones. An immobilized antialkaline phosphatase zone acts as a procedural control; it binds the alkaline phosphatase conjugate and also appears as a blue spot. A further zone contains an immobilized irrelevant murine monoclonal antibody; this detects the presence of heterophile antibodies in samples, particularly human antimouse antibodies.[8] These mimic antigen and bridge the capture and conjugated mouse antibodies, thus giving what appears to be a positive result.

Newer tests require only the addition of sample, thus simplifying the assay protocol and minimizing possible malfunction resulting from operator error. The TestPack PLUS (Abbott Laboratories, Abbott Park, Ill.) one-step pregnancy test illustrates the general principles of the new devices.[64] It uses a colloidal selenium particle (160-nm diameter) labeled with monoclonal anti-α-hCG antibody, which is red and easily visible. Sample (urine) is applied to the sample well and soaks into a glass-fiber pad containing the conjugate. Any hCG in the urine sample combines with the selenium-labeled antibody, and the mixture migrates along a nitrocellulose track to a region where a line of polyclonal anti-hCG antibody and an orthogonal line of anti-β-hCG:hCG complex has been immobilized. The complex captures unreacted selenium-labeled anti-α-hCG

to form a minus sign visible in the viewing window. If hCG is present in the urine sample, then the selenium-labeled anti-α-hCG:hCG complexes bind to the immobilized polyclonal anti-hCG, and a plus sign is formed, denoting a positive result. The remainder of the reaction mixture migrates to the end of the track and reacts with a Quinaldine Red pH indicator in an "end-of-assay" window to signal that the flow in the device has functioned correctly.

A variant of this type of device is the Clearview hCG test (Unipath Diagnostics Inc., Waltham, Mass.). This test uses an absorbent strip that contains blue beads attached to an anti-hCG monoclonal antibody. As urine moves by capillary action through the strip, labeled antibodies are mobilized and move up the test strip, which contains regions of immobilized antibodies loaded with a blue dye. Each strip has separate windows for the positive, negative, and procedural control. If hCG is present at a level of 25 mIU/mL or greater, a blue line becomes visible in the test region window. This region remains clear if the test is negative. A blue line appears in the Reference Region of the result window to show the test is complete and has worked correctly.

Simultaneous multianalyte immunoassays in which two or more analytes are detected in a single assay represent a further means of work simplification in immunoassay. Two different strategies have been developed based on either discrete reaction zones or combinations of different labels. In the Triage panel for drugs of abuse point-of-care test device (Biosite Incorporated, San Diego), simultaneous detection of up to nine drugs is achieved using discrete test zones on a small piece of nylon membrane.[12] Each test zone consists of antibodies for a specific drug immobilized on the membrane surface. This zone captures free gold-drug conjugate from the sample, antidrug antibody, and gold-drug conjugate reaction mixture and appears as a purple band. Combinations of distinguishable labels, such as europium (613 nm, emission lifetime 730 μs) and samarium (643 nm, emission lifetime 50 μs) chelates provide the basis of quantitative simultaneous immunoassays. These two chelates have different fluorescence emission maxima and different fluorescence decay times and thus can be easily distinguished by making measurements at 613 nm, delay time 0.4 ms (europium), and 643 nm, delay time 0.05 ms (samarium). An assay for free and bound prostate-specific antigen and an assay for myoglobin and carbonic anhydrase III are two examples of clinically useful tests combined in this simultaneous assay format.[55,88]

Protein Microarrays

Arrays of hundreds or thousands of micrometer-sized dots of antigens or antibodies immobilized on the surface of a glass or plastic chip are emerging as an important tool in genomic studies and in assessing protein-protein interactions. This format facilitates simultaneous multianalyte immunoassays using, for example, enzyme or fluorophore-labeled conjugates. The arrays are made by printing or spotting 1-nL drops of protein solutions onto a flat surface, such as a glass microscope slide. In a typical sandwich assay, the array on the surface of the slide is incubated with sample and then with conjugate. Bound conjugate is detected using chemiluminescence or fluorescein using a scanning device. The pattern of the signal provides information on the presence and amount of individual analytes in the sample or the reactivity of a single analyte with the range of proteins arrayed on the surface of the slide.[79] (Such devices are discussed in more detail in Chapter 10.)

Interferences in Immunoassays

Immunological assays are prone to interferences, in spite of the use of highly specific antibodies for molecular recognition of the analyte. Falsely low results can occur because of the hook effect at high antigen concentrations (see above). False negative or false positive results are encountered if the sample contains antianimal antibodies. For example, in a two-site sandwich assay for hCG based on mouse antibodies, any human antimouse antibodies (HAMA) present in the specimen will recognize the immobilized mouse capture and mouse conjugate antibodies and form a complex that is indistinguishable from an immobilized capture antibody:hCG:conjugate complex. This leads to a false positive result. A false negative result will be obtained if the HAMA react with either the capture antibody or conjugate to such an extent that specific antibody binding to hCG is prevented. Many different types of circulating antianimal antibodies have been detected (e.g., human antigoat, human antibovine antibodies) and shown to interfere in immunoassays. In practice, this type of interference is minimized by including additives in the immunoassay reagents. Nonimmune serum or IgG from the species used to raise the antibodies has been a popular choice for this purpose.[8,46,49]

OTHER IMMUNOCHEMICAL TECHNIQUES

Other analytical methods of clinical interest that employ antibodies include cytochemical and agglutination assays.

Immunocytochemistry

The use of labeled antibody reagents as specific probes for protein and peptide antigens allows the researcher and pathologist to evaluate single cells for synthetic capability and for specific markers for identification of various cell lines. Immunochemistry in recent years has been rapidly expanded by immunoenzymatic methods, especially with regard to the use of horseradish peroxidase–labeled (immunoperoxidase) assays. Using enzyme labels provides several advantages over fluorescent labels. They permit the use of fixed tissue embedded in paraffin, which provides excellent preservation of cell morphology and eliminates the problem of autofluorescence from tissue. In addition, immunoperoxidase stains are permanent, and only a standard light microscope is necessary to identify labeled fea-

tures. The immunoperoxidase methods are also applicable to electron microscopy. Several approaches for immunoenzymatic assay have been used, including direct, indirect, peroxidase-antiperoxidase, and enzyme bridge methods.

Agglutination Assays

Agglutination assays have been used for many years for the qualitative and quantitative measurement of antigens and antibodies. In an agglutination method, the visible clumping of particulates, such as cells and latex particles, is used as an indicator of the primary reaction of antigen and antibody. Agglutination methods require stable and uniform particulates, pure antigen, and specific antibody. IgM antibodies are more likely to produce complete agglutination than are IgG antibodies because of the size and valence of the IgM molecule. Therefore when only IgG antibodies are involved, it may be necessary to use chemical enhancement or an antiglobulin agglutination method. As with all immunochemical reactions in which aggregation is the measured end point, the ratio of antigen and antibody is critical. Extremes in antigen or antibody concentration will result in inhibition of aggregation.

An incomplete agglutination reaction is one in which the primary reaction occurs, but no or only minimal aggregation of the particles occurs. Many particles, such as erythrocytes and bacteria in solution, have a net negative charge (zeta potential), which causes mutual repulsion.[91] For successful agglutination, the antigen antibody reaction must overcome this normal resistance. In the case of a weak antigen antibody reaction or one in which only IgG is involved, this mutual repulsion may be sufficient to inhibit agglutination completely or partially. In systems in which incomplete agglutination results, enhancement may be achieved by lowering the ionic strength or by introducing polymeric molecules, such as polymerized albumin (5% to 30%), dextran, polybrene, polyvinylpyrrolidone, or PEG.[91]

Hemagglutination refers to agglutination reactions in which the antigen is located on an erythrocyte. Erythrocytes are not only good passive carriers of antigen, but are also easily coated with foreign proteins and can be easily obtained and stored.

Direct testing of erythrocytes for blood group, Rh, and other antigenic types is used widely in blood banks; specific antisera, such as anti-A, anti-C, and anti-Kell, are used to detect such antigens on the erythrocyte surface.

In *indirect* or *passive* hemagglutination, the erythrocytes are used as a particulate carrier of foreign antigen (and in some tests of antibodies); this technique has wide applications. Other materials available in the form of fine particles, such as bentonite and latex, also have been used as antigen carriers, but they are more difficult to coat, standardize, and store. In a related variation of this technique, known as *hemagglutination inhibition,* the ability of antigens, haptens, or other substances to specifically inhibit hemagglutination of sensitized (coated) cells by antibody is determined.

In general, the agglutination methods are quite sensitive but are not as quantitative as other immunochemical methods discussed thus far. Nonisotopic immunoassays, especially EIAs, are as convenient as agglutination reactions and are therefore replacing agglutination methods in many laboratories.

CHAPTER 10

Nanotechnology and Microfabrication

Peter Wilding, Ph.D., F.R.C.Path., F.R.S.C., H.C.L.D.(A.B.B.)

On December 29, 1959, at the annual meeting of the American Physical Society, Nobel Laureate Richard Feynman gave his classic talk entitled "There's Plenty of Room at the Bottom" (http://www.zyvex.com/nanotech/feynman.html). In it, he suggested that ordinary machines could build smaller machines that could build still smaller machines, working step by step down toward the molecular level. To quote, "The principles of physics, as far as I can see, do not speak against the possibility of maneuvering things atom by atom."

Norio Taniguchi at the University of Tokyo coined the term "nanotechnology" in 1974 to describe rapidly emerging and converging technologies that are all based upon the scaling down of existing technologies to the next level of miniaturization. In 1981 Eric Drexler defined molecular nanotechnology as a technology based on the ability to build structures to complex, atomic specifications by means of mechanosynthesis and published the first scientific article on the subject entitled "Molecular Engineering: An Approach to the Development of General Capabilities for Molecular Manipulation."[26] Later in 1992, he authored a book entitled *Nanosystems: Molecular Machinery, Manufacturing, and Computation.*[27]

In 2000 the National Science and Technology Council (NSTC) expanded the definition of nanotechnology to:

"nanotechnology involves research and technology development at the atomic, molecular, or macromolecular levels in the dimension range of approximately 1-100 nanometers to provide fundamental understanding of phenomena and materials at the nanoscale and to create and use structures, devices, and systems that have novel properties and functions because of their small and/or intermediate size. The novel and differentiating properties and functions are developed at a critical length scale of matter typically under 100 nm. Nanotechnology research and development includes control at the nanoscale and integration of nanoscale structures into larger material components, systems, and architectures. Within these larger scale assemblies, the control and construction of their structures and components remains at the nanometer scale." (http://www.becon2.nih.gov/nstc_def_nano.htm).

As articulated by Feynman[37] and Drexler[27] and later by many others,[23,88] nanotechnology and miniaturization in general promise many advantages including economy of scale, ease of operation, reliability of instrumentation, and potential for microscale, massive parallel analyses. Consequently, tremendous efforts in terms of scope, diversity, and rate of progress are being invested in developing miniaturized devices.

From the perspective of the clinical laboratory, miniaturization has been a long-term trend in clinical diagnostics instrumentation.[67] For example, capillary electrophoresis instruments (see Chapter 5) and mass spectrometers have been implemented on microchips of silicon, glass, or plastic. In actuality, however, these devices are not manufactured on a nanometer scale but rather on a micrometer scale. Consequently, this chapter will be concerned with microminiaturized devices whose key components (1) are approximately 100 micrometers in size, (2) are employed in analytical measurement, and (3) require special forms of fabrication designed for microdevices. Although this chapter does not attempt to discuss submicron or molecular structures at the nanometer scale, it should be noted that applications discussed later in it require only nanoliter (nL) quantities of a sample or deal with individual cells that may have cell volume in the picoliter (pL) to nL range.

BACKGROUND

Early efforts to reduce the volume requirements of clinical analyzers resulted in the modification of existing technology to use microvolume quantities of a sample. For example, in the 1970s the Chem-1 Analyzer (Technicon Corp, Tarrytown, N.Y.) was modified to perform a single analysis on a sample volume of only 1.0 μL.[13] Before this date, virtually all clinical analyzers used sample or reaction volumes in excess of 50 μL. By the 1980s concerted efforts to develop handheld devices led to the introduction of the i-STAT system (i-STAT Corp, East Windsor, N.J.; Abbott Diagnostics, Abbott Park, IL.) in 1990; it was one of the first such devices to include microfabricated electrodes and chemical sensors on silicon microchips (Figure 10-1).[33,56] This analyzer featured a functional microsystem employing new fabrication technology that was associated with effective computer-based controls and monitoring capabilities. The use of photolithographic etching technology borrowed from the microelectronics industry illustrated to clinical scientists that microanalytical devices and components could be made in large numbers and be adapted effectively to include chemical components, electrodes, capacitors, and microfluidic features. This illustration by i-STAT laid the basis for numerous other applications to be considered.

Engineering laboratories have been successful in developing miniaturized devices, such as miniature injection valves, actuators, and pumping systems.[11,122,157] Notable efforts with distinct implications for the clinical laboratory community were microdevices for pH measurement fabricated from wafers of silicon.[103,124,130] One of these devices[103] facilitated the measurement of acidic metabolites (e.g., lactic acid) in living cells confined to a flow chamber in silicon. The pH was measured using a light-addressable potentiometric sensor that detects attachment of protons to the chamber surface coated with protonatable silanol and amine groups. Using this device, the changes of metabolism in various forms of cells were monitored. In all of these developments, the exploitation of microfabrication techniques has been essential.

Since these early efforts, the scope of microtechnology has expanded markedly in the early 2000s with developments of applications being driven by the realization of the potential benefit from microtechnology and also from huge investments, particularly to support the science of drug develop-

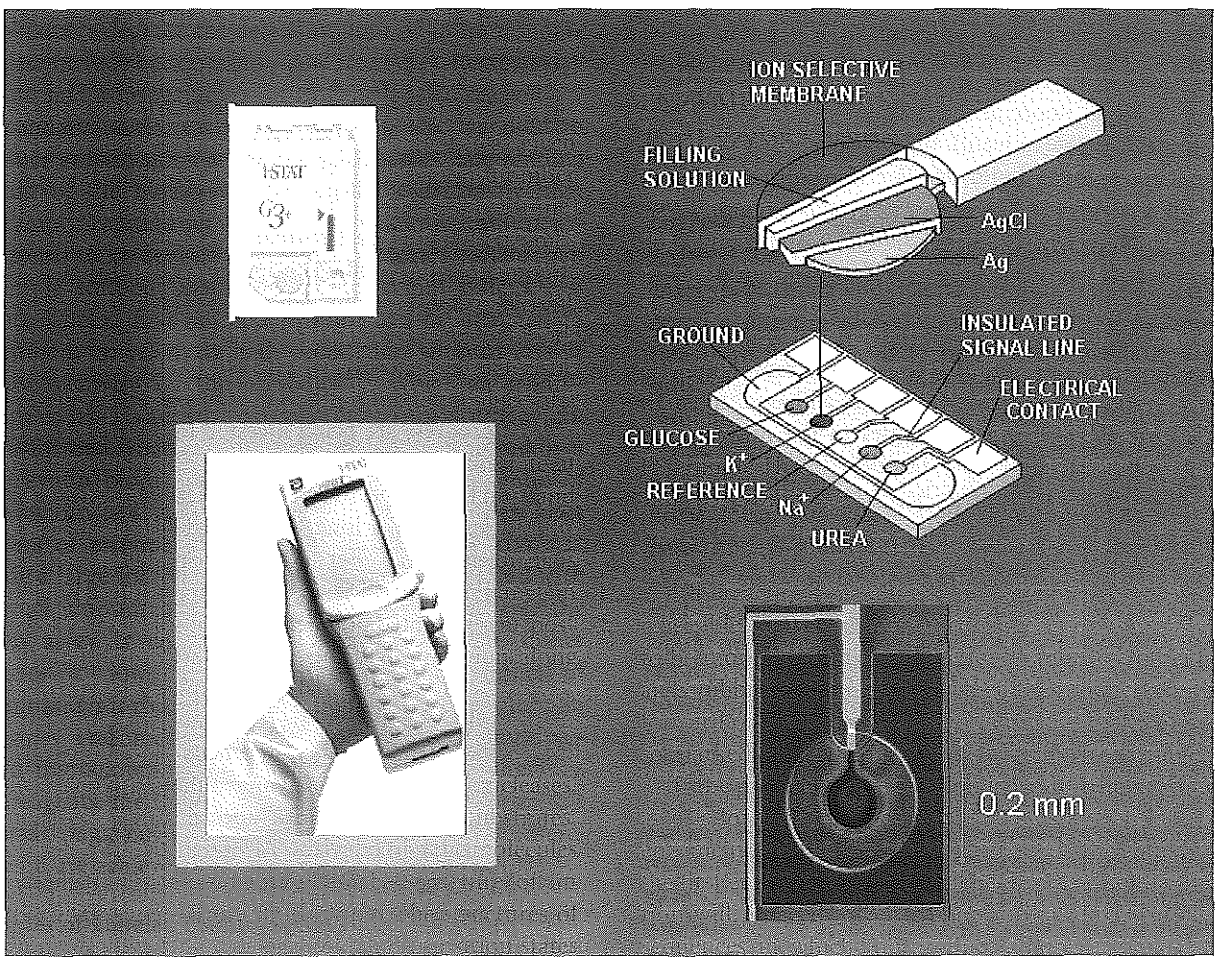

Figure 10-1 The i-STAT system showing a cartridge and the microchip-based electrode assembly. *(Reproduced by permission of i-STAT Corporation, East Windsor, N.J.)*

ment.[65,69,71] Furthermore, hundreds of small companies worldwide have been created to explore and develop applications where the fabrication of microdevices allows for exploitation of new fabricating techniques and the potential benefit of being able to handle and process microsamples.[67] Some of the most notable developments are identified to exemplify the direction of this rapidly developing field. The notable developments are microelectromechanical systems (MEMS), miniaturized total analytical systems (μTAS), microarray type devices for hybridization of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), microfluidic-based devices for capillary electrophoresis, cell-based assays, and numerous other applications.* However, it is realized that clinical laboratorians require systems, not components, for analytical measurement and so the difficulty facing manufacturers has been to produce microdevices that operate competitively within a microenvironment with macrotechnology or conventional technology. The development of microsystems has therefore been delayed because of the necessity to provide associated components, such as valves and sensors that combine to maintain a microenvironment. An additional requirement, not fully appreciated in the early days of microdevice development, is the necessity for appropriate surface chemistry in microdevices where the impact of an adverse charge or chemical grouping on a surface profoundly modifies the behavior and function of a system. Finally, it is important to realize that microtechnology can be limiting when attempting to adapt conventional methods or procedures.

There are numerous excellent articles, books, editorials, and reviews that cover the topic of microtechnology. A short list of some of the most relevant for a clinically oriented reader is presented in Table 10-1; however, attention is drawn to three reviews published in 2002.[3,111,132] Authors of these reviews have pioneered the development of microtechnology, and their reports highlight the scope and magnitude of development that took place in the prior decade.

*References 23, 57, 88, 126, 129, 146.

FABRICATION AND MATERIALS

Computer chips are categorized by their "minimum feature size"—the dimension of the smallest feature actually constructed in the manufacturing process. The minimum feature size is continually getting smaller to pack more circuitry into the same space. For example, advanced chips in production in 2000 had minimum feature sizes of 180 nm, with chips with a size of 90 nm under development.

The concept of a "minimum feature size" is also important in fabrication of microdevices; its actual dimensions are determined by the choice of fabrication process. As discussed below, conventional photolithography (405 or 436 nm) is generally limited to features of approximately 1 μm. Deep ultraviolet (UV) (230 to 260 nm) lithography has a minimum feature size of 0.3 μm, and x-ray and e-beam can be used to generate features as small as 0.1 μm.

In this section, the techniques used to manufacture, drill, and seal microdevices are discussed.

Manufacturing Techniques

A range of techniques and materials are available for the fabrication of microdevices.[2,66] Photolithography on silicon, glass, and plastic surfaces and molding of polymers are commonly employed processes used to fabricate microdevices. Other processes in use or under investigation include embossing, laser ablation, molding, and atomic force microscopic etching.

Photolithography

Photolithography is the process of transferring geometric shapes on a mask to the surface of a silicon wafer. It involves

a series of steps.[2,106] First, a photo mask defining the shapes of the structures to be etched on the silicon wafer is generated from larger drawings that can be accurately duplicated and reduced in size using computer-based programs (Figure 10-2). The silicon wafer is then oxidized to produce a thin surface layer of chemically resistant silicon dioxide that will allow coating with a photo resist material. The wafer is then evenly coated with a polymeric photo resist using a spin-coating procedure and patterned using a photo mask and a UV light source. The photo resist is either a positive resist (photo resist in areas of the wafer exposed to light is rendered soluble) or a negative resist (photo resist in areas of the wafer unexposed to light is rendered soluble). The insoluble polymerized resist remaining on the wafer forms an image of the photo mask on the silicon dioxide surface of the wafer. The wafer is now ready to have the oxide etched away either by a wet or dry etching process.

Wet Etching

Wet etching covers any form of etching where etching is performed by immersing the silicon wafer or glass or plastic surface in a bath of the chemical etchant. The chemical etchants are either isotropic or anisotropic. Isotropic etchants such as hydrofluoric acid (HF) will etch a given material at the same rate whatever direction they are etching in, and are less used because they are difficult to control and etch underneath the protective resist. By contrast, anisotropic etchants will etch at different rates in a given material depending on a number of factors, the most useful one being the crystal structure and orientation. Etching of glass is usually achieved using HF. Microstructures in glass can also be formed by laser ablation techniques.

Figure 10-3 illustrates how the angles of etching can be controlled using an anisotropic etchant. The most widely used anisotropic etchant is potassium hydroxide (KOH). Most etchants will not etch impure silicon at the same rate as pure silicon; this fact can be used to the advantage of the

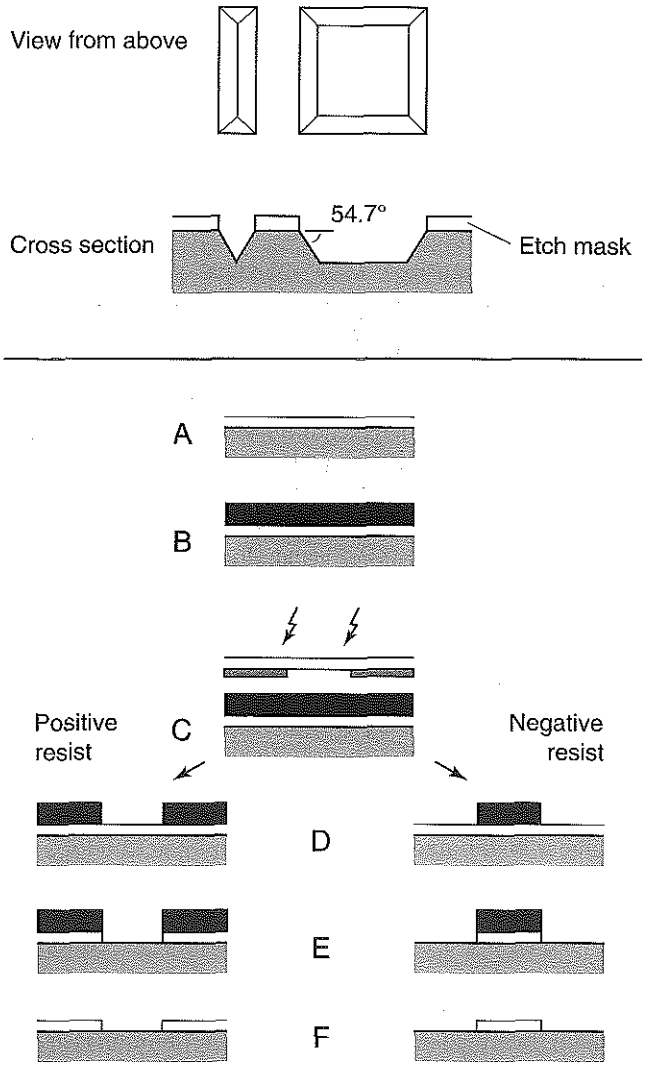

Figure 10-3 Schematic of the etching process used in photolithographic-based fabrication. Upper box: Anisotropic etch of silicone by KOH using silicon nitride mask. Lower box: **A,** Silicon wafer (hashed) with etch mask (white). **B,** Application of photo resist (black) onto etch mask. **C,** Exposure of photo resist through photo mask. **D,** Positive and negative photo resist after development of resist. **E,** Removal of etch mask. **F,** Removal of photo resist, leaving either the pattern present in the photo mask or its opposite patterned into the etch mask.

engineer. An example of this would be that if a small part of the silicon substrate is doped with boron, the doped section will not be etched as fast as the normal silicon; if an isotropic etchant is used, the silicon beneath the boron doped area will be etched away. The main disadvantage with using this doping method is that it alters the electrical properties of the silicon so that fabricating and microelectronic devices on the same substrate will be much more difficult.

Dry Etching

This type of etching does not use any chemicals directly on the wafer; instead the most popular method involves accel-

erating ions toward the wafer to be etched. These ions will etch more in the direction in which they are traveling. This method is called reactive ion etching (RIE). RIE is an anisotropic etching method because the direction of the etching controls the rate of etching (see Figure 10-3). In the final steps, the photo resist and the silicon oxide layers are removed to give the final etched silicon wafer. By using multiple masks and sacrificial layers that permit undercutting to produce movable components, it is possible to fabricate complex multicomponent structures on the surface of a silicon wafer. All of these fabrication steps are performed in a clean room environment, thus permitting the production of sterile devices suitable for in vivo or clinical application.

Molding of Polymeric Materials

The LIGA process was developed at the Institut für Mikrostrukturtechnik (IMT) at the German University of Karlsruhe, in the early eighties under the leadership of W. Ehrfeld. LIGA is an German acronym (Lithographie, Galvanoformung, Abformung) standing for the main steps of the process; it involves deep x-ray lithography,[142] electroforming, and plastic molding. These three steps make it possible to mass produce microcomponents at a low cost.

In practice, the LIGA process provides a way to manufacture a mold for a microstructure. It consists of the following steps. First, a resist-coated substrate is patterned using a mask and a source of synchrotron radiation (oriented x-rays). Secondly, after development, the resist structure is electroplated. This electroforming produces a metal microstructure (a negative replica of the structure), and this is then used as the mold for the final structure. Advantages of the LIGA process are that high aspect ratios are attained (e.g., lateral dimensions of a few μm and vertical dimensions of up to 1000 μm), and the molds can be used to prepare multiple replicas of the structure in a variety of materials (e.g., polyimide, polymethylmethacrylate [PMMA]).[8]

Direct molding using a silicon master and a thermoplastic fluoropolymer (e.g., Hostaflon) at 150 °C and at a pressure of 50 kg/cm^2 has been employed to fabricate channels for performing electrophoresis. The plastic molded part was then clamped between two plates to complete the sealing of the channel. Other methods have also been employed to create microfluidic devices in various polymeric materials.[54] Laser ablation of poly dimethylsiloxane (PDMS) has been used to create elastomeric molds that pattern structures,[48,125] or nickel molds produced from a silicon master pattern device from acrylic polymers[89] or polystyrene.[160] Copolyester microfluidic devices have also been constructed using this principle for use in ultrafiltration of food contaminants and for use in drug screening.[59] Other devices for capillary electrophoresis of DNA samples have been made by compression molding of polycarbonate against a silicon master.[79,83] In some of these devices using polymeric materials, such as polyimides, the molding has been coupled with metallization layers to allow the production of electrodes inside or outside the fluidic channels.[76,91] With all of these structures, there is a need for bonding or sealing processes that allow the formation of channels or chambers.

Incorporation of Electronic Components

Another requirement in certain microchips is the incorporation of electronic components, such as electrodes (see Chapter 4).[138] So-called bioelectronic chips have been constructed that use arrays of platinum electrodes (80 μm in diameter) coated with streptavidin. By modifying the charge applied to the electrodes, molecules such as DNA or RNA are differentially attracted to, or displaced from, the electrode surfaces.[16,42]

Drilling

Mechanical, ultrasonic, and laser drilling are processes also used to fabricate chambers in microdevices. Laser drilling is particularly suited for drilling very small size holes (e.g., less than 2 μm using a deep UV excimer laser).[5] This type of drilling is of increasing importance for the manufacture of devices used for high throughput systems that are used for ion channel studies on isolated cells in the pharmaceutical industry where exact holes of approximately 1 μm are required.[152] In these situations, the contours of the small holes being created and the surrounding surface area are critical to success, and the demanding criteria are rarely met by silicon with its crystalline structure.

Chambers have also been drilled through glass by means of an electrodischarge process in which the glass is submerged in an alkaline solution (e.g., NaOH) and a needle (30-μm diameter tip) contacting the glass and a negative potential applied (40 volts).[122]

Bonding and Sealing

Sealing structures to produce liquid-tight enclosures (chambers and channels) is a key step in the fabrication of a microdevice. Several different processes are available depending on the materials employed. However, in nearly all cases some method of surface cleaning is necessary before the bonding process.

Surface Cleaning

One of the most common methods of cleaning surfaces for subsequent sealing is the use of the so-called "piranha clean," which involves emersion in a mixture of H_2SO_4 and H_2O_2 (3:1) followed by washing with deionized water. When this method is unsuitable (e.g., the device contains metal electrodes), then alternative methods—such as treatment of the surfaces with oxygen plasma[141] or laser radiation[143]—have been used.

Anodic Bonding

Pyrex glass has been bonded to silicon using an anodic bonding technique.[1] With it, the thermal expansion coefficients of the two materials are similar thus residual stress after bonding is minimized. Operationally, a mirror-polished, clean flat piece of glass is placed on top of a clean

piece of polished silicon and heated to near the annealing point of the glass (180 °C to 500 °C). A negative voltage of 200 to 1000 volts is applied by attaching electrodes to the silicon (anode) and glass (cathode). The DC voltage creates an electric field between the two surfaces and pulls them into contact. This electrostatic attraction arises as follows: glass behaves as an electrolyte at high temperature, and there is a migration of ions (mostly Na^+ from the dissociation of Na_2O) toward the cathode that leaves a residual negative charge on the glass surface adjacent to the silicon surface. The actual bond is believed to be chemical, possibly a thin layer of silicon dioxide. Other materials have also been bonded using this process, including gallium arsenide–glass and silicon-silicon. The latter is achieved by first sputtering a thin layer of Pyrex glass (4 μm thick) onto one of the silicon surfaces.[61] Glass has also been bonded to glass using a simple thermal cycle process[35] or without thermal treatment if rigorous cleaning is used[20] or using a UV curable glue at room temperature.[55]

Eutectic Bonding

This method is used for bonding two silicon surfaces. A thin layer of gold is coated onto the surface of one of the wafers, or a thin sheet of gold-silicon or gold-tin mixture is placed between the two surfaces (a preform). The assembled device is then clamped together and heated in a vacuum chamber above the eutectic temperature for the particular materials (e.g., eutectic temperature for Si/Au is 36 °C). The preform melts and a diffusion process (gold into the silicon surface) leads to the formation of a silicon alloy between the contacted surfaces. As this cools, a bond is formed between the two surfaces.[61]

Other Bonding Methods

Other methods of bonding include direct bonding[127] and clamping.[118] However, most of these methods preclude the treatment of channels or chambers within the device before bonding. Several methods have been employed for bonding polymeric materials. These include pressure between aluminum plates[59] and the use of adhesives or materials modified by UV light.[29]

MICROFLUIDICS

Microfluidics is a key functionality in the success of microdevices. It is defined as a branch of physics and biotechnology that studies the behavior of fluids at the microscale and mesoscale, volumes thousands of times smaller than a common droplet. It also concerns the design of systems in which such small volumes of fluids will be used. For example, the gene chips and labs-on-a-chip are based on the transport of nanoliter or picoliter volumes of fluids through microchannels within a glass or plastic chip.

The success of microfluidics research is seen in the innovative designs of microdevices that have been constructed so that either stable fluid flow or chaotic mixing is achieved depending on the requirement. To ensure adequate mixing, numerous systems have been developed. Some simple systems are based on the positioning of baffles in the flow stream; others achieve the mixing with complex three-dimensional serpentine structures[81,82] or use of closed loop devices.[158] Furthermore, the design of microfluidic devices that facilitate rapid analysis of sequential samples without carryover or the separation of particulate materials (e.g., blood cells or bead preparations) has required meticulous study of flow characteristics. Early studies in 1992 showed that electroosmotic pumping or electrokinesis could be used to control the movement of solutions in microcapillaries.[52,87] Later in 1994, it was demonstrated that using pressure, blood could be pumped through microchannels on a silicon microchip[148] without causing obstruction of the channels. Subsequently the science of microfluidics has expanded greatly to the point where this subject is regarded as a scientific discipline. In many devices, especially those involved with capillary electrophoresis, there is a requirement to accurately meter and mix nL volumes of liquids with great precision followed by transfer of a small aliquot to a detection area.[86] These activities are now characterized in terms of fluid dynamics, and future designs will be based on the understanding of these phenomena. An example of the progress made in such designs is illustrated in Figure 10-4.[46,109] Application of this type of design dramatically diminishes deterioration of sample integrity as it flows through a microchannel.

As the designs of microdevices have developed, there has also been an increasing demand to exploit this technology for high throughput screening, especially within the pharmaceutical industry. In an effort to accommodate this demand, creative designing has been necessary. In Figure 10-5 a microchip is shown that accommodates 96 capillary electrophoresis channels in one device.[117] Other developments have resulted in a device that allows for up to 384 parallel channels on one glass microchip (wafer).[32] However, the problem with such designs is achieving convenient peripheral equipment that allows (1) filling of the multichannel devices; (2) the parallel, or sequential, monitoring of the fluid flow; and (3) the detection and quantitation of the various reactions. As a result, it is important to ensure that a sample injection into microdevices occurs with as much precision and accuracy as the process requires. Ensuring that a sample is injected as a distinct bolus has initiated the design of numerous injection systems that are dictated by the pumping system being used.[41] Electrokinetic pumping (see Chapter 5) tends to employ T-junctions where the fluid flow is controlled by application of differential voltages, and pressure-based systems use rapid injection from syringes operated by pumps.

VALVING SYTEMS

To successfully implement microtechnology systems into the clinical laboratory, where accuracy and precision are

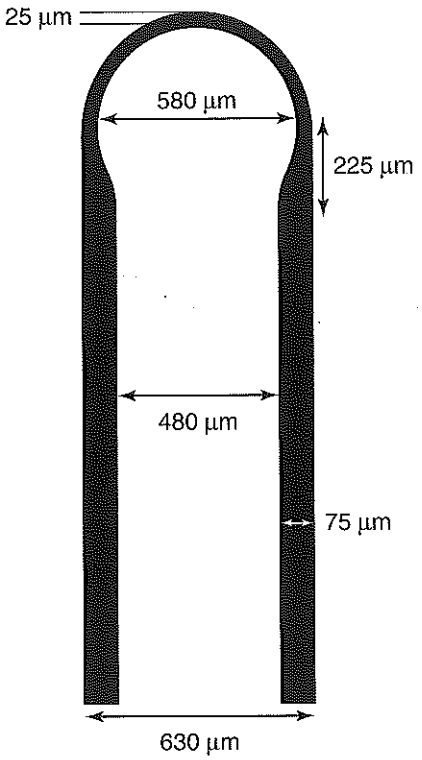

Figure 10-4 Design of an asymmetric turn used in microchip-based capillary electrophoresis system constructed in glass. The design facilitates the maintenance of sample integrity during flow in a microchannel around a curve. The dimensions are indicated on the figure and are taken from the tops of the channels. The channels were filled with black ink for contrast. *(From Ramsey JD, Jacobson SC, Culbertson CT, Ramsey JM. High efficiency, two-dimensional separations of protein digests on microfluidic devices. Anal Chem 2003;75:3758-64.)*

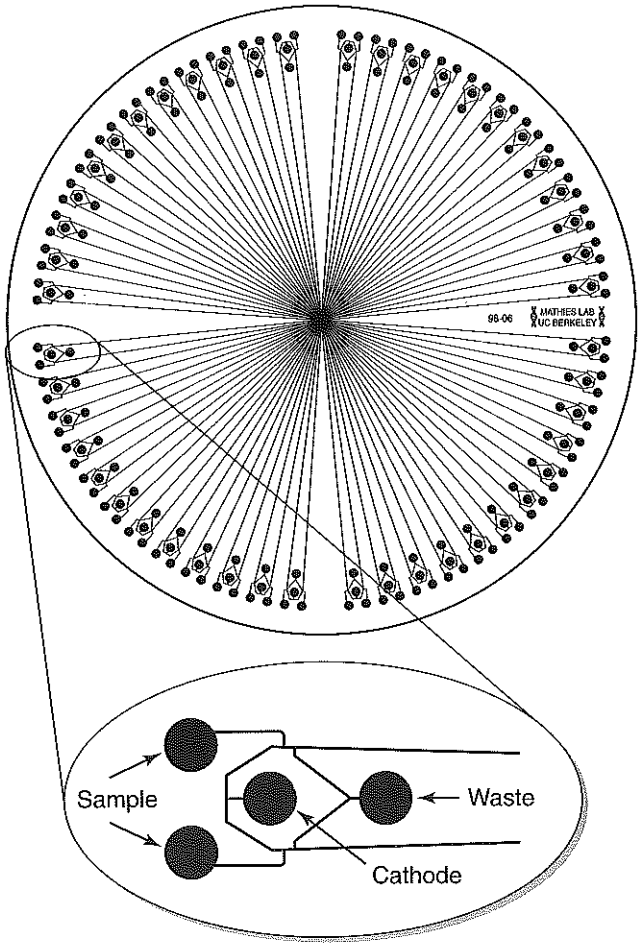

Figure 10-5 Design of a complex microfluidic device for parallel capillary electrophoresis. Figure shows the mask pattern for a 96-channel radial capillary electrophoresis microplate in glass. The separation channels with 200 μm twin-T injectors were masked to 10 μm width and then etched to form 110 μm wide by approximately 50 μm deep channels. The diameter of the reservoir holes is 1.2 mm. The distance from the injector to the detection point is 33 mm. The glass substrate is 10 cm in diameter. *(From Shi Y, Simpson PC, Scherer JR, et al. Radial capillary array electrophoresis microplate and scanner for high-performance nucleic acid analysis. Anal Chem 1999;71:5354-61.)*

mandatory requirements, there is basic requirement in many instances for accurate and precision volume metering of fluids and reagents.[115] In many reported applications on microchips, this requirement has not been included, or the requirement is circumvented by the use of internal standards.

However, to realize a practical and cost-effective system for biomedical applications, a microvalve system that will process human whole blood is essential. To date, most microvalve systems have been microfabricated from silicon,[123] although valves using plastic membranes have also been developed.[159] Chip-based microvalve systems have been classified as either active microvalves (with an actuator) or passive (check) microvalves (without an actuator).[123] The miniaturization of the active microvalve systems is restricted by the size of the actuator.

Actuators used for the active microvalve systems include solenoid plungers,[128] bimetallic actuators,[58] and piezoelectric actuators.[34,120,121] However, numerous other principles have been employed, such as springs,[120] pneumatic pressure,[99] or electrostatic[45] or electromagnetic forces.[155] Other microvalve systems have been developed that employ a variety of principles, including hydrogel bistrips that are activated and deactivated by pH change[156] or a bistable gate valve, actuated by electrolytically generated gas bubbles.[102] However, none of these systems have been widely adopted even though one of them may well provide the basis of future analytical platforms.

The characteristics of the silicon chip–based active and passive microvalve systems have been reviewed.[159] As expected, the sizes of the passive microvalve systems were generally smaller than the active microvalve systems, and the response time of the active microvalve systems ranged from 5 milliseconds to 10 seconds, whereas many of the passive microvalve systems based on electrokinetic forces in

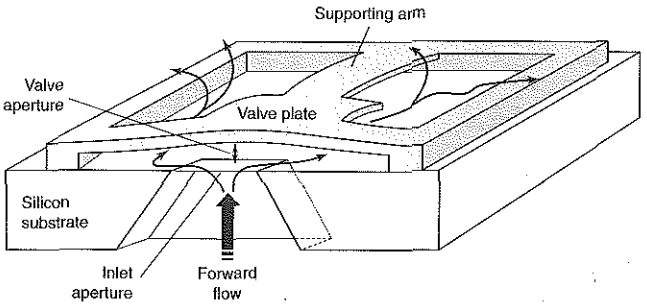

Figure 10-6 Example of a microfluidic valve constructed in silicon (1200 × 1200 μm) with an etched aperture to form the inlet for gas or liquid. The movable valve plate is supported by four polycrystalline-silicon arms, 400 μm long and 200 μm wide, attached to the silicon substrate. *(From: Bien DCS, Mitchell SJN, Gamble HS. microchannels can operate in microseconds. Silicon chip–based microvalve systems for medical and biomedical applications are still limited, especially a microvalve system that is suitable for whole blood handling. Developing an effective microvalve for use with body fluids and suspensions of particulates (e.g., whole blood) represents a major challenge because passive types of valves based on electrokinesis will not handle these types of fluids. Overcoming this challenge is a vital step toward developing practical totally integrated microfluidic systems for blood analysis. A partly disposable three-way microvalve employing a silicon membrane also has been developed that claims to be suitable for whole blood handling using pneumatic actuation.[99] However, no data on whole blood handling in this valve are yet available. Integrated systems aimed at the clinical market are under development and prototype systems have been reported[17,47,119,149] for a variety of purposes. An example of a microfluidic valve is shown in Figure 10-6.

APPLICATIONS

As previously stated, the scope of applications of nanotechnology and microtechnology in science, industry, and medicine is extremely wide and diverse (Table 10-2). Here we wish to emphasize those applications with relationships or relevance to biomedicine, even though many of the scientists involved in the field work strictly in the disciplines of electroengineering and mechanical engineering, microfluidics, and industrial physics. Examples are drawn from the wide assortment of applications to illustrate the direction and capability of this technology. Some of the applications in different fields employ the same principles or technology—such as microchip-based electrophoresis,[131] microarrays, or thermal cycling—but they are discussed according to their clinical subdiscipline.

GENOMICS

Microdevices and microtechnological developments have had their greatest impact in the field of genomics, and thousands of papers have been published describing their application in this arena. In essence the involvement covers several main areas, including techniques for DNA and amplification, hybridization arrays, sample preparation, and detection and quantitation of nucleic acids and small polynucleotides (see Chapters 36 and 37).

Early reports by Northrup et al[96] and Wilding, Kricka, and colleagues[17,150] established that DNA amplification using the polymerase chain reaction (PCR) was possible in a microchip. Both groups used elementary microchambers etched in silicon and demonstrated that effective amplification could be achieved. Subsequent reports indicated that this technology, including microfluidics, provided effective, reliable, and precise (CV less than 10%)[150] nucleic acid amplification on a microchip.[73,148] Using elementary microchips, this degree of performance of PCR on a chip was attained with volumes of 10 to 50 μL of PCR reaction mixtures containing target DNA, Taq-polymerase, DNA primers, and the requisite nucleotides that were heated by external thermocyclers. Early efforts were successful, but the reports lacked evidence of the reliability, precision, and sensitivity of amplification, and it soon became apparent that other issues, such as surface chemistry[149] and good heating control,[95,151] had to be resolved before effective systems could be developed. Based on earlier work using glass capillary-based devices and forced air heating,[151] it was assumed that very short cycling times for PCR would be achieved. However, forced air for thermocycling seems an unlikely basis for more complex devices.

Since the early demonstrations of microchip-based PCR, numerous authors have reviewed the topic and forecast the

direction that this technology will follow.* The large number of potential applications in the clinical laboratory based on DNA amplification made this an attractive field for commercial reasons. Other reviews† have described the role of microchip-based PCR and reverse transcription PCR (RT-PCR) in DNA sequencing and genetic analysis and the problems of process control and the state of the art.

It was projected in the mid-1990s that chip-based devices would become more complex and incorporate features that would facilitate sample preparation, amplification, and amplicate detection. As a result, the next generation of chip-based devices not only brought complexity but a clear awareness of the limitations and hurdles that microchip-based technologies present. As of 2005, the majority of the benefits of using microchip-based devices for PCR are still perceived, rather than realized. It has been assumed since the first illustration of microchip-based PCR in the early 1990s that features such as low-reagent consumption, low-volume sample requirements, and rapid cycle times would be a consequence of this technology. However, the ability to couple the PCR process with other features such as sample preparation and amplicate detection quickly initiated a drive to the design and construction of integrated devices, that ultimately should provide more convenient and cheaper methods in the many fields in which molecular biology is practiced. The expected economy of scale of manufacturing has yet to be realized, but it is assumed that the pattern will follow that of the electronics industry where millions of microdevices are produced at low cost. This is a realistic projection, because it is likely that the microdevices that ultimately serve the needs of the analyst and researcher will eventually incorporate much of the degree complexity of electronic microchips. Furthermore, because of the relative simplicity of the biological microchips and the roles they will serve, it is probable that the manufacturing processes will be more likely based on plastic than silicon.

Many commercial and academic centers that are exploring this technology have already demonstrated that DNA targets from several biological systems, including the human genome, viruses, and microbes, can be amplified by PCR on miniaturized devices.[4,62,116] Newer developments have been directed toward total systems (Figure 10-7) that incorporate sample preparation, amplification, and detection.[18,60,74,139,140] These developments achieve greater convenience and shorter cycle times for the PCR. Another approach used to achieve faster cycle time has been to use a microfluidic chip that pumps nL quantities of PCR-reaction mixture through a circular channel arranged over three heaters that facilitate denaturation, annealing, and extension during the PCR.[80]

The fields in which the growth of microchip-based genomics have first emerged relate to drug development in the pharmaceutical industry where determination of inhibition or enhancement of nucleotide replication is important. Other early products include devices designed for the defense industry, where the detection and identification of toxic agents is desirable. Another key area is the provision of products that facilitate the parallel operation of PCR on microsamples for the life sciences where production of sufficient amplicate is a requisite for sequencing studies.

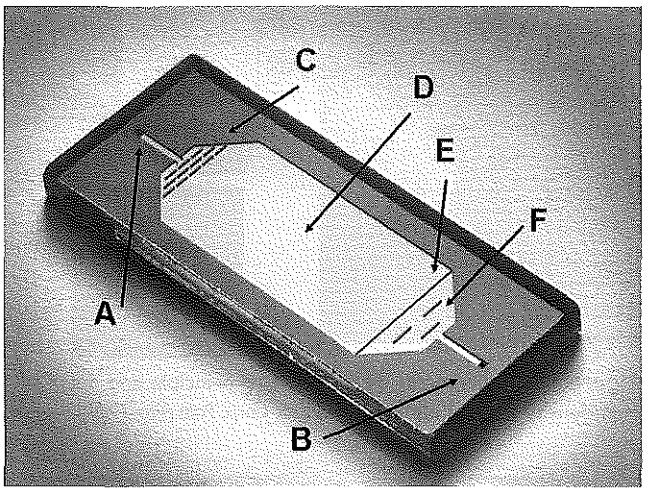

Figure 10-7 Silicon-glass microchip (14 × 35 mm) for cell isolation and PCR. By flowing 1.0 μL of whole blood into the chamber, WBCs can be isolated on the filter bed. PCR is performed after releasing the cells back into the main microchip chamber. Thermocycling is achieved by external heating. *A*, Entrance port to chip. *B*, Exit port from chip. *C*, Deflectors for forward flow. *D*, Chip chamber that is 80 μm deep and passivated with 2000 angstroms of thermal oxide. *E*, Filter bed having 667 pillars (10 × 20 μm, 3.3 μm gaps). *F*, Exit baffles.

Hybridization Arrays

Hybridization arrays are now widely used in genomic research (see Chapter 37). Primarily these arrays have been developed to meet the growing demands of pharmaceutical research. However, there are few academic centers today that do not have core facilities to prepare low- and high-density arrays to meet the requirements of academic research studying gene expression.

The basic principle underlying hybridization arrays is the immobilization of a DNA probe onto a planar surface of glass, silicon, or polymer material. The length of the DNA probe may vary greatly depending on the nature or role of the array. Attachment of probes to the surface has become a complex science involving coupling reagents, spacer molecules, and customized surface chemistry. Hybridization generally requires single-stranded DNA as both a probe and a sample. To facilitate detection of successful hybridization, a fluorescent tag is added to the sample. Moreover the density and size of individual spots on any array have varied from less than 10 on a glass slide to over 10,000 per square cm in

*References 9-11, 14, 15, 30, 67, 68, 97, 107, 110, 144.
†References 3, 62, 97, 98, 112, 132, 162.

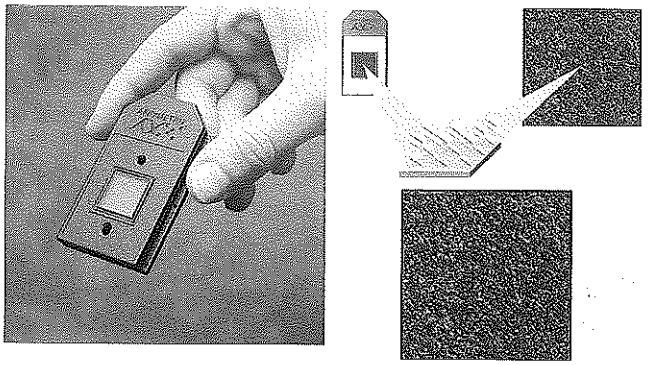

Figure 10-8 Microarray device showing principle and detail of high-density array. *(Courtesy Affymetrix Corp, Palo Alto, Calif.)*

certain commercial products. Methods for creating or manufacturing arrays vary from simple spotting of a DNA probe solution with a micropipette to complex photolithographic techniques, as used by the Affymetrix Corp., that allow for the synthesis of each probe in a spot to create oligonucleotides up to 20 base pairs or more (Figure 10-8).[6,38,39]

The conditions under which the hybridization process takes place have varied from 24 hours in certain static systems to a few minutes in some of the newer devices with microfluidic flow and mixing features. Detection of the hybridization is effected with an array reader that quantitates the level of fluorescence and identifies the location of the spot. When the array is high density, the reader frequently involves confocal microscopy and considerable computing capacity. Because partial hybridization can occur, usually caused by use of an inappropriate length of probe or sample DNA, the fluorescent signal is modified. Therefore the interpretation of high-density array information is complex. In efforts to improve the specificity of hybridization, many techniques have been developed, which include the use of microarrays created on electrodes that facilitate the selection of appropriate targets and the elimination of interfering molecules or other materials. A technique of so-called electronic stringency has been developed to achieve this by the Nanogen Corp.[16,114] Other expanding technologies based on hybridization arrays are those used for gene expression and gene mapping.[30] For this procedure, the assessment of sample quality is required to prevent the inappropriate use of expensive arrays. As a result, convenient microchip-based capillary electrophoresis devices have been developed that facilitate the assessment of DNA and RNA preparations and that are capable of providing a fast and accurate determination of the size and quantity of DNA or RNA fragments. One device (The Agilent 2100, Agilent Technologies, Palo Alto, Calif.) analyzes up to 12 specimens in less than 30 minutes using only 1 μL of a sample[94,101] and incorporates up to 13 internal standards. This device has also been adapted to facilitate testing of protein solutions.

Nucleic Acid Sequencing

The human genome project has been successful in the sequencing of the human genome (see Chapter 36) using conventional technology. However, it is now apparent that advancements made in microtechnology will provide another opportunity for the biologist eager to sequence DNA. Using long capillary channels fabricated in microfluidic devices of glass or silicon, several workers have demonstrated successful sequencing of up to 800 base pairs with a reported accuracy of 99%. The microdevices involved used 16-channel electrophoresis arrays,[82] 40-cm-long microchannels,[63] or a radially conformed 96-channel microcapillary electrophoresis system.[100] Using such systems, a dramatic improvement in the speed of sequencing has been achieved, resulting in parallel sequencing separations of 450 bases in less than 15 minutes.

Drug Detection and Assay

The huge commercial potential for the development of assays for therapeutic drugs or drugs of abuse that employ microsamples and disposable microdevices has yet to be realized. However, it is clear that assays for these compounds will be performed in a convenient manner and will impact the clinical laboratory in the near future. An early report showed that serum theophylline could be measured using immunoassay and capillary chromatography on a microchip.[133] Subsequent work illustrated the successful measurement of imipramine and desipramine in human plasma using capillary electrophoresis– and mass spectrometry–based microchips[25] and drug screening assays for barbiturates and phenobarbital antibodies.[59] The problem with these assays is that no device has yet been produced that meets the requirements of "user friendliness" necessary for the busy clinical laboratory or the rigid specifications demanded for recording quality assurance data.

Protein Chips

It is expected that microdevices that facilitate studies on the existence and classification of protein chips will have a great impact on the emerging field of proteonomics (see Chapter 43). For example, microarrays printed or spotted with proteins have already been developed.[75,85] However, problems were encountered obtaining the prerequisite specificity of binding between the antigens and antibodies. In addition, arrays containing thousands of phage libraries or unique clones have now been constructed using glass, hydrogels, or gold,[28,49] but again problems with identification were encountered. It has been found that some proteins incur structural changes when attached to solid surfaces. These efforts have also demonstrated that "blocking proteins" are useful to diminish nonspecific binding. In addition, new immobilization strategies and techniques are being developed that optimize the binding of the receptor protein (antibody or antigen) to the surface of a chip. As with the DNA array, detection is usually accomplished with fluorescent

tags,[84,161] but other methods, including radiolabels or mass spectrometry,[43] have been employed.

Immunoassay for Antibodies and Peptides

One of the earliest efforts of qualitative measurement of a protein (human serum albumin) in a microchip-based device was based on bead agglutination in a microchamber (approximately 10 μL).[147] Subsequently, several quantitative immunoassays have been performed using microchip electrophoretic systems that permit separation and quantitation of free- and bound-labeled antigens in competitive assays (see Chapter 5). Most are carried out in channels micromachined into fused silica substrates. Early work on quantitative assays achieved measurement of cortisol in serum.[64] The assay used cortisol labeled with fluorescein and an argon laser detector at 488 nm and required only 80 μL of a 40× dilution of serum as the sample. Other capillary electrophoresis–based assays for a variety of antibodies have also been developed that include immunoglobulins (IgG, IgA, and IgM), antibovine serum albumin, and antiestradiol.[19]

Isolation of target proteins using immobilized antibodies or proteins on bead or microchannel surfaces has also been successfully demonstrated. Other assays for IgG and IgA using magnetic or polystyrene microbeads in microchip assays have demonstrated that viable alternatives to capillary electrophoresis do exist. In another microchip method, polystyrene beads were introduced into a glass microchannel and then human secretory immunoglobulin A (s-IgA) adsorbed on the microbead surface. This in turn was reacted with colloidal gold conjugated anti-s-IgA antibody and detected by a thermal lens microscope.[113] This system creates an environment that shortens the antigen antibody reaction to less than 10 minutes and has a level of detection of approximately 1 μg/mL, far below the requirements of a clinical assay.

A 2002 variation of a microchip-based immunoassay employs amperometric detection of the redox tracer ferrocene after separation by capillary electrophoresis.[137] A direct assay (noncompetitive) involves (1) mixing the ferrocene-tagged antibody and an antigen analyte, (2) rapid electrophoretic separation of labeled free antibody and the labeled antigen and/or antibody complex, and (3) a downstream anodic detection of the ferrocene tracer at a gold-plated carbon screen-printed electrode detector. The competitive assay integrates precolumn reactions of the labeled antigen and the target antigen with the antibody with electrophoretic separation of the free- and bound-labeled antigens, along with amperometric detection of the redox tag. In this study, the authors state that the use of a redox tracer offers the advantages of simplified protocol, wider linear range, higher stability, and higher separation efficiency compared with an analogous use of enzyme tags. Assays for direct mouse-immunoglobulin G (IgG) and the competitive 3,3′,5-triiodo-L-thyronine (T3) were accomplished within less than 150 and 130 seconds, respectively, and offer minimum detectable concentrations of 2.5, 10, 12 and 1, 10, 6 g/mL, respectively.

The technique of isoelectric focusing has proven to be a useful tool in protein chemistry, and this too has been adapted to the microchip. Using 7-cm-long channels in glass microchips (200 μm wide and 10 μm deep) mixtures of Cy5-labeled peptides can be focused in less than 30 seconds.[53] This same procedure has also been applied to plastic microchips made from PMMA by laser ablation and shown to focus mixtures of peptides labeled with rhodamine green.[53,108] Results for this type of microchannel isoelectric focusing are available in less than 5 minutes compared with traditional techniques that take over 1 hour.

The scope of assays using microchips has also encompassed lipoproteins. Low-density lipoprotein analyses have been performed in an uncoated glass microchannel capillary electrophoresis chip.[14] Analyses using mixtures of lipoproteins isolated from blood have been completed in under 25 seconds. However, no convenient method is yet available for the clinical laboratory.

Enzymology

Several enzyme-based assays have been developed for microdevices but few, if any, are applicable to native biological specimens such as plasma or serum. This is mainly because the bulk of assays developed are carried out in devices employing capillary electrophoresis using electrokinesis as the driving force in the microdevice, which is unsuitable for liquids with high concentrations of ions, proteins, metabolites, or particulates (e.g., cells). However, it is anticipated that future convenient assays will be developed that will facilitate use of biological specimens, such as serum or plasma, using pressure-driven systems in microchips are perfected. The motivation for developing enzyme assays in microdevices has been derived mainly from the necessity to perform assays for multiple enzymes in high throughput screening of compounds that are candidates for therapeutic drugs. For this reason, multiplexed enzyme assays have been developed for groups of kinases and phospholipases using a single-use capillary electrophoresis type of microchips.[153] Also, successful use of microchip-based devices, again using capillary electrophoresis, has been developed for measurement of β-galactosidase, and inhibitory action on this enzyme[51] and acetylcholinesterase.[50] A generic microchip method has also been described that uses enzymatic detection for glucose, ethanol, theophylline, and amino acids.[134] Other microchip-based assays have also been developed for the measurement of protein kinases,[22] leucine aminopeptidase,[164] insulin, and glucose.[135]

Metabolites

Because the bulk of assays in the clinical chemistry laboratory stem from the various metabolites, the potential for microchip-based assays is extremely large. The possibility that multiple assays will be carried out using microsamples with minimal use of reagents has many implications for the

clinical laboratory and the diagnostics industry. However, apart from an impressive list of assays available on the i-STAT device, which includes Na, K, chloride, urea nitrogen, creatinine, glucose, lactate, and ionized calcium,[56] the number of assays developed to date is few, and most rely on the use of microchip-based capillary electrophoresis with various forms of detection.

Simultaneous assays for glucose, uric acid, and ascorbic acid have been demonstrated in aqueous solutions of the analytes using a glass microchip system of capillary electrophoresis employing amperometric detection with a silver–silver chloride electrode.[136] Microchip-based capillary electrophoresis technology has also been adapted to measure carnitine and selected acylcarnitines in urine extracts by using mass spectrometry as the detection method.[24] A method using similar technology but with electrodes for detection has been used to measure homocysteine and glutathione in plasma.[104] This method measures homocysteine up to levels of 50 μMol/L, well above the healthy concentrations of 5 to 15 μMol/L.

An assay for uric acid in urine employing a PDMS and/or glass microchip for capillary electrophoresis has also been developed.[36] This device can achieve separation and quantitation of uric acid in less than 30 seconds and a linear response over a range of 0 to 100 μM/L. To facilitate this measurement, dilutions of urine of the order of fiftyfold to seventy-fivefold were required. Other similar devices for the renal markers creatine, creatinine, p-aminohippuric acid, and uric acid in urine,[135] and a microchip-based method for zone electrophoretic analysis of oxalate in urine have been reported.[163]

Cell Handling and Cell Culture

Using the microenvironment of a microdevice to facilitate cell culture and the study of cellular behavior has resulted in several applications. For example, the incubation process of *E. coli* in a gas-permeable PDMS microfluidic device has been monitored by fluorescence[92]; also screening for agonists and antagonists in cultured cells has been achieved by monitoring calcium flux.[21] In addition, using specifically designed filter systems or electrodes, it was shown that cells could be isolated by size or charge from other populations or surrounding media followed by a variety of treatments, such as immunoattachment, lysis, or DNA and RNA release. For example, the ability to create filter systems with selected pore sizes for isolation of white blood cells (WBCs) has been demonstrated starting with volumes of whole blood less than 5 μL.[40,146] Figure 10-9 illustrates the nature of a microfilter used for this purpose.

Additional applications include the study of red blood cell (RBC) mobility[7] and chemotaxis and locomotion of WBCs in a confined environment.[12]

Other Applications

Other avenues of miniaturization are being pursued that have medical applications. These include the opportunity to manipulate analytes and cells to (1) provide improved methods of reagent and sample transfer; (2) mix aliquots using techniques such as electrokinesis[110]; (3) isolate or separate macromolecules or cells by filtration[146] and electrical charge; (4) ensure electronic stringency[16]; and (5) use nanoparticles to measure biomolecules.[105]

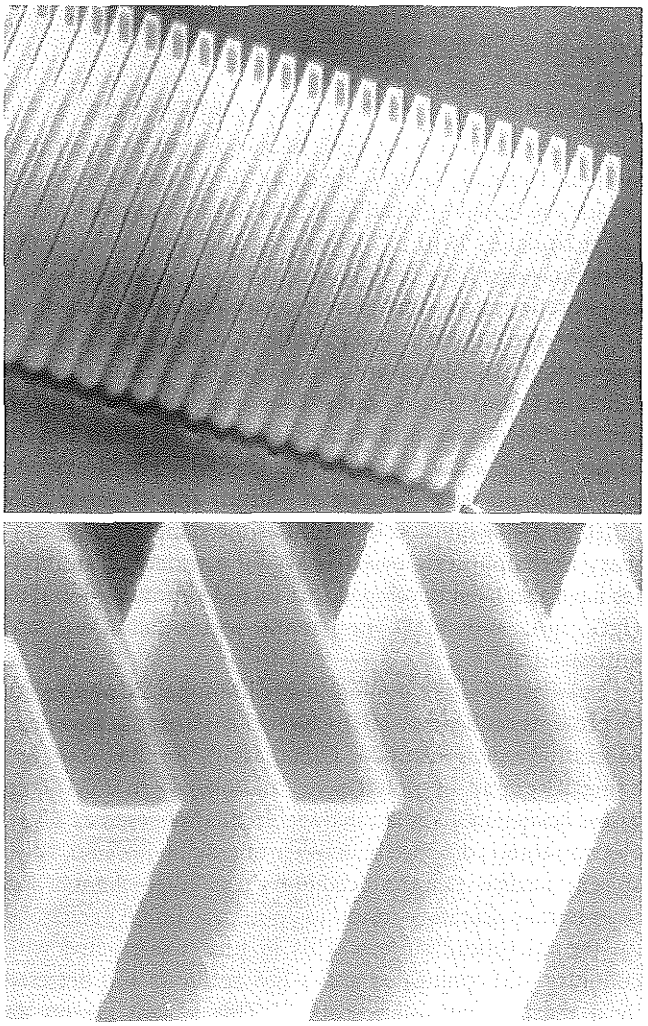

Figure 10-9 Microfiltration device made in silicon by reactive-ion etching. Upper picture shows low magnification of electron micrograph. Each pillar is 90 mm high. Lower picture shows detail of the gaps between filter elements (3.5 mm). Each pillar is 20 mm long and 10 mm wide, which allows easy passage of RBCs but precludes large granulocytes. *(Courtesy Wilding P, Kricka LJ, University of Pennsylvania.)*

SURFACE CHEMISTRY ISSUES

An early discovery during the development of microchip PCR was the importance of surface chemistry in microchip operation and design.[119,149] This work demonstrated that PCR in silicon microchips was severely inhibited if the surface chemistry was unsuitable. These workers noted that the increase in surface area in microchips, relative to volume,

could be twentyfold greater compared with conventional tubes used for PCR. Moreover, if the surface was only partially coated or existed as silicon, silicon nitride, or certain other substances, then it was very difficult to achieve reproducible or adequate amplification. However, successful and reproducible amplification could be achieved if the surface was subjected to coating with a suitable passivating layer (e.g., 2000 angstroms of silicon oxide). Passivation of the silicon surface has also been achieved with polymeric coatings of the microchip channels and chambers[93] or by silanization of glass microchips followed by a coating of polyacrylimide.[74]

Other studies have sought to employ other substrates with fewer problems, but the inherent one of increased surface-to-volume ratio always applies. One of the approaches has been to incorporate substances such as polyethylene glycol (PEG), polyvinylpyrrolidone (PVP), or epoxy compounds that significantly reduce or eliminate binding of analytes or key reagents to surfaces.[44] Others have used silanization followed by coating of the channels or chambers with polymeric compounds.[93] Additionally, microchip-based capillary electrophoresis devices constructed from PDMS and glass have been modified with a three-layer biotin-neutravidin sandwich coating, made of biotinylated IgG, neutravidin, and biotinylated dextran. By replacing biotinylated dextran with any biotinylated reagent, the modified surface can be readily patterned with biochemical probes, such as antibodies.[77,78]

LIMITATIONS OF MICROTECHNOLOGY

The limitations of microtechnology are invariably related to the concentration of the analyte or type of cell under study. If the device is only capable of receiving microliter quantities, then the final signal strength being measured will depend on the inclusion of an amplification process (e.g., PCR) or the ability to detect extremely low levels of analyte concentration or type of cell identification. For example, only 0.5 μL of whole blood are necessary to allow for isolation of 500 WBCs, more than sufficient to provide genomic DNA for mutation detection by PCR. Similarly, submicroliter quantities of protein or DNA solutions provide adequate material for analysis by capillary electrophoresis (see Chapter 5). However, if the aim is to identify and isolate an infected WBC in whole blood that is present at an incidence of only 1 in 10 million, then quantities in excess of 10 mL of whole blood may be required just to encounter 5 cells. This does not provide the ideal situation for a microdevice. Another key limitation, namely the impact of surface chemistry, has been addressed in a previous section.

An application in microchip technology that highlights the limitation of the sole use of microtechnology is the use of a microfabricated filter to enhance the enrichment of fetal cells in a preparation that will be used for genomic studies.[126,154] In this study, the goal was to provide a sample that contains 5 to 50 nucleated red blood cells (n-RBCs) of fetal origin so that chromosomal or genomic studies could be performed. The starting specimen for this isolation and/or enrichment procedure is 20 mL of maternal blood, and so the 5 to 50 fetal n-RBCs are being isolated from a matrix containing approximately 100 billion adult RBCs, 100 million adult WBCs, and 1.4 g of protein. The encouraging data resulting from this work is achieved only because microtechnology is used in combination with preparative steps using conventional technology (cell agglutination and immunoprecipitation with magnetic beads). This example illustrates that successful application of microtechnology in the clinical field will probably result in hybrid systems that exploit both conventional and microtechnology.

THE FUTURE

The future of nanotechnology and microfabrication in the clinical field, particularly where it will impact the clinical laboratory, is difficult to forecast. However, because the necessity to reduce analytical costs is a constant theme there is little doubt that products of this technology will be implemented and used. Moreover, as the demand grows for increased effort at the point of care, coupled with the growing demand to achieve low-cost, high-throughput screening for malignancies and other diseases, it is inevitable that microtechnology will be a developing science for many years. Forecasting which subdisciplines in laboratory medicine will be the first to benefit is more difficult. The advances made in microcapillary electrophoresis, nucleic acid amplification, and the many detection techniques suggest that molecular pathology will benefit first, but that many other subdisciplines will soon follow. The application of nanostructures and the manipulation of molecular architecture to facilitate clinical assays have already commenced with the use of nanosized beads as labels for ligands or antibodies and for the modification of surface chemistry.[70,71] However, it will be necessary for these technologies to surpass current achievements using present day techniques and to compete on an economic basis in the ever demanding world of healthcare.

CHAPTER 11

Automation in the Clinical Laboratory*

James C. Boyd, M.D., and
Charles D. Hawker, Ph.D., M.B.A., F.A.C.B.

The term "automation" has been applied in the field of clinical chemistry to describe the use of laboratory instruments and specimen processing equipment to perform clinical laboratory assays with only minimal involvement of the technologist.

The development of automated instruments for the clinical laboratory began in the 1950s at the same time as the demand for tests escalated dramatically. The availability of automated instruments enabled laboratories to process a much larger workload without a comparable increase in staff.[23] The evolution of automation in the clinical laboratory has paralleled that in the manufacturing industry, progressing from fixed automation—whereby an instrument performs a repetitive task by itself—to programmable automation—which allows it to perform a variety of different tasks—to intelligent automation, where individual instruments or systems are able to self-monitor and respond appropriately to changing conditions.

One benefit of automation is a reduction in the variability of results and errors of analysis by eliminating tasks that are repetitive and monotonous for a human and that can lead to boredom or inattention. The improved reproducibility gained by automation has led to a significant improvement in quality of laboratory tests in recent years caused largely by the combination of skillfully designed automated instrumentation with good analytical methods and effective quality assurance programs.[37] In recent years many small laboratories have consolidated into larger, more efficient entities in response to market trends for reducing costs. The pioneering work to automate these merged laboratories has pointed to new avenues in laboratory automation. No longer is automation being used simply to assist the laboratory technologist in performing tests, but it now extends to (1) processing and transporting specimens, (2) loading them into automated analyzers, and (3) assessing the results of the performed tests. Automation of these additional functions is basic to the future prosperity of the clinical laboratory.

In this chapter, we discuss the principles that are applied to automate the individual steps of the analytical process both in individual analyzers and in the integration of automation throughout the clinical laboratory. We provide examples of these principles as implemented in commercially available chemistry, hematology, immunoassay, and nucleic acid systems; point-of-care (POC) analyzers; and automated specimen processing systems.* Definitions of terms used in the automation of clinical chemistry have been published by the International Union of Pure and Applied Chemistry (IUPAC).[48]

HISTORICAL OVERVIEW

Automation of laboratory assays has occurred incrementally over the past 50 years.[13,15] Key to the successful automation of these assays was the incorporation of continuous flow and

*The authors acknowledge the original contributions of Ernest Maclin and D.S. Young upon which portions of this chapter are based.

*Many times throughout this chapter, we refer to various commercially available analyzers. The addresses and web addresses of the companies that offer these analyzers are available on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/.

discrete processing steps in the design of automated instruments and systems for use in clinical laboratories. Ancillary developments of note include the development of laboratory information systems, robotics, and the concepts of total and modular automation.

Processes Used in Automation

Types of liquid processing steps used to automate laboratory assays include continuous-flow and discrete processing.

Continuous-Flow Analysis

The development of the continuous-flow analyzer by Leonard Skeggs in the 1950s was a landmark step forward from the manual performance of laboratory analyses.[82,83] Skeggs' pioneering device, eventually marketed as the Technicon AutoAnalyzer, was a single-channel, continuous-flow batch analyzer that provided one result per analyte for each specimen at a rate of 40 to 60 specimens per hour. In continuous-flow systems, the reaction occurred in tubing that served as both flow container and cuvet. Specimens and reagent were combined using a roller pump that pushed them through a fluid manifold designed specifically for each assay. To control reagent and specimen volumes, different internal diameter pump tubing was used. Mixing was achieved by running the reactants through coils. Carryover of one specimen to the next was minimized by injecting air bubbles at regular intervals into the specimen stream. Air bubbles were removed as the reactant stream reached the photometer where absorbance readings were taken. Temperature control, if necessary, was supplied by immersing coils of tubing in temperature-regulated water baths. Timing of the reaction was controlled by the distance the stream traveled in the tubing. Protein-free filtrates of the reaction mixture could be provided using dialyzers. Continuous-flow analyzers remained a mainstay of routine laboratory analysis for more than 20 years. The second and third generations of continuous-flow analyzers—the Technicon SMA 12/60 and the SMAC—were able to provide multiple test results on the same specimen.

Discrete Analysis

Discrete analysis, in contrast with continuous-flow analysis, allows each specimen in a batch its own physical and chemical space, separate from every other specimen. Early discrete analyzers, such as the 1970 vintage robot chemist, mimicked the steps of manual human analysis.[57] Subsequently, many discrete analyzers were developed and are still widely used in clinical laboratories. Centrifugal and random access analyzers are examples of instruments that use discrete processing.

Centrifugal Analyzers

Centrifugal analyzers were invented and developed in the early 1970s by Norman Anderson and his colleagues at the Oak Ridge National Laboratory with funding provided by the U.S. Atomic Energy Commission, National Institute of General Medical Sciences, and National Aeronautics and Space Administration.[5,80] With a centrifugal analyzer, discrete aliquots of specimens and reagents are pipetted into discrete chambers in a rotor. The specimens are subsequently analyzed in parallel by spinning the rotor and using the resultant centrifugal force to simultaneously transfer and mix the aliquots of specimens and reagent(s) into radially located cuvets. The rotary motion is then used to move the cuvets through the optical path of an optical system. Under control of an integrated computer system, multiple absorbance readings are taken from each cuvet and resultant software used to calculate enzyme activity or substrate concentration. Although early centrifugal analyzers analyzed multiple specimens for a single analyte in parallel, the development of technologies to select different optical wavelengths rapidly enabled centrifugal analyzers to perform several analyses in parallel at different wavelengths. Thus the rotor could contain specimens for several different tests at the same time and the appropriate tests on each specimen could be scheduled by keyboard entry or bar coded labels on specimen tubes.

Random-Access Analyzers

Random-access analyzers perform analyses on a batch of specimens sequentially with each specimen analyzed for a different selection of tests. The tests performed in the random-access analyzers are selectable through the use of different containers of liquid reagents, different reagent packs, or different reagent tablets depending on the analyzer. This approach permits measurement of a variable number and variety of analytes in each specimen. Profiles or groups of tests are defined for a specimen at the time the requested tests are entered into the analyzer by means of a keyboard (used in most systems), by instruction from a laboratory information system in conjunction with bar coding on the specimen tube, or by operator selection of appropriate reagent packs. Like centrifugal analyzers, random-access analyzers incorporate computers and are able to take multiple absorbance or reflectance measurements for each assay. In addition, enough self-diagnosis features are programmed into each analyzer's software to allow the technologist operating the instrument to leave the instrument for brief periods of time. This latter feature, termed "walk-away" automation by the manufacturers, offered the first opportunities for a single technologist to operate more than one analyzer at a time.

Most current chemistry and immunoassay analyzers are random-access analyzers. Manufacturers have steadily improved the mechanical reliability of these systems, and provided software that allows technologists to operate the analyzers easily.

Laboratory Information Systems

Integral to the automation of the clinical laboratory was the development of the laboratory information system (LIS) that first appeared in laboratories in the latter part of the

1960s and early 1970s (see Chapter 18). At first these systems served primarily as a way of generating consolidated laboratory result reports. However, LISs quickly evolved into tools to capture all test requests, to manage laboratory work flow, and to improve the quality of laboratory results. Particularly important in the improvement of laboratory quality was the development of direct electronic interfaces between laboratory analyzers and the LIS that supplanted the necessity for manual transcription of results from analyzer to laboratory report. The modern LIS has extensive software for supporting the entire clinical laboratory enterprise (see Chapter 18). In hospital settings, the LIS may also be interfaced to other clinical systems, such as admitting, billing, electronic medical records, and pharmacy.

Robotics

Robotic technology was first applied in the clinical laboratory in the 1980s as an outgrowth of developments in industrial robotic automation, which started a quarter of a century earlier. Microprocessor-controlled robot arms developed in the early 1980s allowed development of robotic laboratory workstations capable of carrying out programmable multistep specimen manipulations. The programmability of these new devices gave them flexibility to be adapted to many different assay and specimen-handling approaches. This new generation of robots was first used in laboratories for automated specimen preparation in chromatographic and spectroscopic assays.

Types of Automation

Types of automation developed for use in the clinical laboratory include total and modular automation.

Total Laboratory Automation

A laboratory constructed by Dr. Masahide Sasaki and his laboratory technologists in the early 1980s at the Kochi Medical School in Nankoku, Japan, provided an early model of total laboratory automation.[77] In Sasaki's laboratory, conveyor belts transported carriers containing patient specimens to various analytical workstations throughout the laboratory, and mobile robots moved the empty carriers back to a central location. When these carriers arrived via the conveyor belt at each workstation, automated pipettors aspirated serum from each tube for the required laboratory assays. At some workstations, one-armed stationary robots performed pre-programmed pipetting and dispensing steps on the patient specimens to accomplish more complex preanalytical processing steps.

Sasaki's laboratory provided the first glimpse of a total laboratory automation system. A total laboratory automation (TLA) system is generally constructed on a large scale and includes some or all of the preanalytical automation functions, such as centrifugation of blood specimens, aspiration of serum from centrifuged tubes into aliquot tubes, decapping of tubes, splitting of specimens into additional aliquot tubes, bar code labeling of aliquot tubes, and sorting of tubes according to predetermined laboratory destinations.[7,8] In addition, a TLA system also includes a transport system, such as a conveyor that delivers tubes to specific automated analyzers that are mechanically interfaced to the system for automated sampling and analysis. TLA systems also often include a tube recapping machine, a delivery location for specimens that are not analyzed on interfaced analyzers, and an automated storage system for specimens for which testing has been completed (for possible repeat tests or additionally ordered tests). TLA will be discussed in depth later in this chapter.

Sasaki's vision of an integrated automated laboratory coupled with the demonstration of successful robotic applications by other groups created much enthusiasm for robotic automation of the laboratory in the early 1990s.[12] For example, enthusiasts touted the ability of robotic systems to improve the quality and reproducibility of testing, while providing shorter test turnaround times, reduced costs of testing, and improved worker safety. Because commercially developed TLA systems were very expensive, all but the largest laboratories were slow to adopt the new technology.

Modular Automation

By the mid-1990s, manufacturers had begun to market modular automation products in which selected modules—such as analyzers, ion-selective electrodes (ISE), and rack lanes or tracks—could be integrated together to meet the requirements of the individual laboratory.[33] Examples of modern modular systems are shown in Table 11-1. Although modular automation was marketed to the laboratory community much more successfully, there was also widespread recognition that automation of the preanalytical steps (particularly sorting, centrifugation, and aliquoting) would yield the greatest labor (and cost) savings. These steps have been focal points for new automation development.

Laboratory Automation Systems

The development of TLA and modular automation required the development of computer systems known as laboratory automation systems (LAS) with extensive software to support these systems in the clinical laboratory. For a more detailed description of the relationships between an LAS, LIS, automation equipment, and laboratory analyzers, the reader is referred to the National Committee for Clinical Laboratory Standards (NCCLS) standard on laboratory automation communications.[61]

INDIVIDUAL STEPS IN THE ANALYTICAL PROCESSES

The individual steps required to complete an analysis are often referred to as "unit operations." They include the following:

1. Specimen acquisition
2. Specimen identification
3. Specimen delivery to laboratory

TABLE 11-1 Examples of Modular Systems with Key Parameters

System Name	Modules	Throughput Range, Results per Hour	Key Common Elements	Module Assembly	Comments
SYNCHRON CX7	Analyzers	825	Sampler and computer	At factory	Combines the CX3 and CX4
MODULAR	D, P, E modules	170-10,000	Rack lanes, loading station, and computer	At factory and in field	Multiple common analytical modules can be used
WorkCell	Analyzers	1650 chemistry and 240 immunochemistry	Track and computer	At factory	Combines the 1650 and Centaur
LX4201	Analyzers	2880	Computer	At factory	Combines two LX20 analyzers
AU5400 Series	Analyzer(s)	3200-6600	Rack transfer lanes and computer	At factory	Combines up to 3 analyzer modules and 2 ISE modules

4. Specimen preparation
5. Specimen loading and aspiration
6. On-analyzer specimen delivery
7. Reagent handling and storage
8. Reagent delivery
9. Chemical reaction phase
10. Measurement approaches
11. Signal processing, data handling, and process control

In this section, we describe these operations individually and intersperse examples of how they have been automated in terms of operational and analytical performance. In most automated systems, these steps are usually performed sequentially, but in some instruments they may be combined and occur in parallel.

Specimen Acquisition

Techniques used to acquire specimens for subsequent analysis in the clinical laboratory are discussed in Chapter 2, but few devices have been developed that automate these techniques. There is, however, ongoing work to develop approaches to automate collection of blood specimens traditionally collected by finger stick or phlebotomy. For example, various new hand-held devices for automated monitoring of blood glucose have been designed to sample blood from sites on the body such as the fingertip, forearm, thigh, and calf (see Chapters 4 and 25). One such device applies a small vacuum, lances the skin, transfers blood onto an electrochemical test strip, and measures glucose.[35]

Additionally, Zivanovic and Davis have evaluated a robotic system for blood sampling that presses a flat-headed probe against the surface of the skin and uses force and/or position profiles to determine the location of a vein.[94] When a needle is inserted, the characteristic force and/or position profile, on puncturing the vein wall, is distinctive enough to implement automatic needle withdrawal to prevent overshoot. The authors plan to develop both an autonomous blood sampling robot and a force-feedback surgical trainer.

Specimen Identification

Typically the identifying link between patient and specimen is made at the patient's bedside, and it is imperative that this connection be maintained throughout the transport of the specimen to the laboratory, its subsequent analysis, and the preparation of a report. Many technologies are available for automatic identification and data collection purposes, including labeling, bar coding, optical character recognition,[11] magnetic stripe and magnetic ink character recognition, voice, radiofrequency identification, touchscreens, light pens, handprint tablets, optical mark readers, and smart cards. Historically, labeling was the technology used for identification purposes. However, bar coding is now the technology of choice.

Labeling

In many laboratory information systems, electronic entry either in the laboratory or at a nursing station of a test order for a uniquely identified patient generates a specimen label bearing a unique laboratory accession number.[11] A record is established that remains incomplete until a result (or set of results) is entered into the computer against the accession number. The unique label is affixed to the specimen collection container when the blood is drawn. Proper alignment of the label on the collection container is critical for subsequent specimen processing when using bar coded labels. Arrival of the specimen in the laboratory is recorded by a manual or computerized log-in procedure. In other systems, the specimen is labeled at the patient's bedside with the patient identification and collection information and enters

the laboratory with a requisition form; there it is assigned an accession number as part of the log-in procedure, which may or may not be computer implemented.

After accessioning, specimens undergo the technical handling processes. For those processes requiring physical removal of serum from the original tube, secondary labels bearing essential information from the original label must be affixed to any secondary tubes created. The secondary labels are generated at the time of accessioning by a special, usually computerized device.

For analyzers that do not automatically link specimen identity and aspiration, the sequence of results produced must be linked manually with the sequence of entry of specimens. Some analyzers print out or transmit to a host computer each result or set of results from a specimen, either by position of the specimen in the loading zone or by the accession number programmed to that position.

Bar Coding

A major advance in the automation of specimen identification in the clinical laboratory has been the incorporation of bar coding technology into analytical systems.[4,10,85,90,93] In practice, a bar coded label (often generated by the laboratory information system and bearing the specimen accession number) is placed onto the specimen container and is subsequently "read" by one or more bar code readers that have been strategically placed at key positions in the analytical train. The resultant identifying and ancillary information is then transferred to and processed by the system software.

Unequivocal positive identification of a specimen can be achieved in analyzers with bar code readers in less than 2 seconds. Advantages of the use of coded labels that can be automatically scanned and identified by the analyzer include: (1) elimination of work lists for the system, (2) prevention of mix ups in the placement of tubes in the analyzer or during sampling, (3) analysis of specimens in a defined sequence, and (4) absence of possible tube mix up when serum must be transferred into a secondary container.[87] The reader is cautioned, however, that most automation systems require individual container identification instead of relying only on the LIS accession number. The NCCLS automation standards also require unique container identification.[59-63] Since a given patient order could consist of two or more different types of specimen, all bearing the same accession number, the use of unique container identification is the only way to ensure that an automation system delivers the correct type of specimen to the appropriate analyzer or destination. Most manufacturers have incorporated computer software to detect the different symbologies. The bar code detector can "autodiscriminate" or automatically recognize and read codes in one of several common symbologies so that operator intervention is not required. Examples of bar codes that are used in chemistry analyzers are presented in Figure 11-1.

Initiating bar code identification at a patient's bedside ensures greater integrity of the specimen's identity in an analyzer. Systems to transfer information concerning a patient's identity to blood tubes at the patient's bedside have been introduced in some hospitals and several companies are now offering these systems (Becton, Dickinson & Co., Bridge Medical, Inc., Lattice, McKesson, and Systemme INFORMATICA). One difficulty in applying these systems is the necessity to cross traditional administrative boundaries; this can create conflict with established procedures that are beyond the control of the laboratory staff. However, the Food and Drug Administration has issued a proposed rule that would require matching of bar codes on medications and blood products to patient bar code wristbands.[29] Thus, most healthcare facilities are now adopting these systems (and solving their administrative issues), which enable the laboratories to ensure accurate and reliable specimen identification.

Both one- and two-dimensional (2-D) bar coding systems are now available. Of the two, one-dimensional bar codes have been the most widely used in the clinical laboratory.

One-Dimensional Bar Codes

A one-dimensional bar code is defined as "an array of rectangular bars and spaces that are arranged in a predetermined pattern following unambiguous rules to represent elements of data that are referred to as characters."[6] A bar code is transferred and affixed to an object by a "bar code label," which carries the bar code and, optionally, other human-readable information. "Symbology" is the term used to describe the rules specifying the way the data are encoded into the bars and spaces. The width of the bars and spaces, and the number of each, is determined by a specification for that symbology. Different combinations of the bars and spaces represent different characters. On passing a bar code scanner over the bar code, the light beam from the scanner is absorbed by the dark bars and not reflected; the beam is reflected by the light spaces. A photocell detector in the scanner receives the reflected light and converts the light into

an electrical signal that can be digitized. A one-dimensional bar code is "vertically redundant" in that the same information is repeated vertically—the heights of the bars can be truncated without any loss of information. In practice, vertical redundancy allows a symbol with printing defects, such as spots or voids, to be read.

Different types of symbologies are used to encode information into one-dimensional bar code labels.[1,4,66,90] Some are numeric only (Universal Product Code [UPC], European Article Numbering [EAN] system [now also called IAN for International Article Numbering], Interleaved 2 of 5), some are of fixed length (UPC-A is 12 digits, UPC-E is 6 digits, EAN-13 is 13 digits, and EAN-8 is 8 digits), and some have both numbers and alphabetic characters (Code 93, Code 128, and Code 39). Code 128 allows the encoding of all 128 ASCII characters. Standards for symbologies have been developed and the Health Industry Business Communications Council endorses the use of six of them.[44] The NCCLS has published a standard for the use of bar codes to support clinical laboratory automation.[60] This standard recommends that Code 128 replace all other symbologies in laboratory automation systems such as Code 39, Codabar, and Interleaved 2 of 5 by December 31, 2003. The standard also specifies bar code symbol and label placement zones for tubes of various lengths (66 mm, 75 mm, and 100 mm) and specifying the minimum widths of a narrow bar and the quiet zone. (See http://www.taltech.com/TALtech_web/resources/intro_to_bc/bcsymbol.htm for examples).

Two-Dimensional Bar Codes

As its name implies, a 2-D bar code stores information along the height and the length of the symbol and is designed to place a portable database in as little space as possible.[6] The term "matrix code" applies to 2-D codes that code the data based on the position of black spots within a matrix. Each black element is the same dimension and it is the position of the element that codes the data. Moving-beam laser scanners and charge-coupled device (CCD) scanners are used to read 2-D labels. More than 20 different 2-D symbologies have been developed for encoding 2-D labels. They include Codablock, Code 16K, Code 49, Data Matrix, MaxiCode, Portable Data File (PDF) 417, and Softstrip, each of which allows for more information to be encoded into a 2-D label than can be encoded into a one-dimensional bar code label. For example, the PDF 417 allows for between 1000 and 2000 characters to be encoded per symbol, with an information density of between 100 and 340 characters. Few, if any, clinical laboratories are employing 2-D codes because the data that could be contained in those codes, such as patient name, age, sex, collection date and time, specimen type, ordered tests, etc., are widely desired to be human readable. Additionally, the price of 2-D readers is much higher than 1-D bar code scanners.

Identification Errors

Specimen identification and test ordering errors occur frequently in the clinical laboratory and emanate from errors that occur in the specimen collection and accessioning process.[9,73,86] With the 1999 publication of the Institute of Medicine (IOM) report, *To Err is Human: Building a Safer Health System*,[50] there has been increasing scrutiny of identification errors in medical practice. The IOM report urges improved understanding of the causes of errors in the healthcare system and development of approaches using computerized and other "mechanical" support systems to decrease error rates.

Operationally, many opportunities arise in the clinical laboratory for mismatching specimens and results.[37] The risks begin at the bedside and are compounded with every processing step that a specimen undergoes between collection from the patient and analysis by the instrument. The risks are particularly great when hand transcription is invoked for accessioning, labeling and relabeling, and making load lists. An incorrect accession number or one with a transposition of digits, or a load list with transposed accession numbers, may cause test results to be attributed to the wrong patient. An additional hazard exists when specimens must be inserted into certain positions in the loading zone defined for them by a load list. Human misreading of either specimen label or loading list may cause misplacement of specimens, calibrators, or controls. In one study, automatic reading of bar coded labels was found to reduce the error rate from 1 in 300 characters (for human entry) to about 1 in 1 million characters.[66]

Specimen Delivery to Laboratory

Several methods may be used to deliver specimens to the laboratory, which is often in a location distant from the patient. These include courier service, pneumatic tube systems, electric track vehicles, and mobile robots. In some laboratories, phlebotomists may also bring specimens with them as they return to the laboratory.

Courier Service

Human couriers have been extensively used to transport specimens from collection sites to the laboratory and between laboratories. Although in general reliable, there are problems with courier service. For example, human delivery is a batch process, and couriers usually only service a given pickup point at specified times. Arrangements for stat pickup can be made, but this adds costs to the analytical process and delays the reporting of results. In addition, specimen breakage or loss can occur with manual handling of specimens.

Pneumatic Tube Systems

Pneumatic tube systems provide rapid specimen transportation and are quite reliable when installed as point-to-point services. However, when switching mechanisms are introduced to allow carriers to be sent to various locations, additional mechanical problems may arise and cause carriers to be misrouted. Although pneumatic tubes have been reported to damage specimens because of rapid acceleration or decel-

eration,[39,70] and have limited carrying capacity, they have been found to be cost effective.[38]

Electric Track Vehicles

Electric track vehicles have a larger carrying capacity than pneumatic tube systems and do not appear to have problems with damaging specimens by acceleration and/or deceleration forces. Some systems maintain the carrier in an upright position by use of a gimbal (a device that permits a body to incline freely in any direction or suspends it so that it will remain level when its support is tipped). Compared with pneumatic tube systems, electric track vehicles usually require a larger station for loading and unloading, and this fact often limits where a station may be placed. If the station is not located directly in the central laboratory, additional staff may be necessary to unload the carts and transport the specimens to their final destination, and the electric track system may not achieve its desired goal of rapid specimen transport.

Mobile Robots

Mobile robots have been used successfully to transport laboratory specimens both within the laboratory[32,47] and outside the central laboratory.[71] Further studies are required to establish the usefulness of mobile robots for specimen transport, but it is already apparent that mobile robot transportation will have many of the same limitations as the human messenger (e.g., batched specimen pickup and time delay in notifying of necessity for pickup). In a busy laboratory setting, however, delivery of specimens to lab benches by a mobile robot can be more frequent than human pickup and has been shown to be cost effective.[17]

Specimen Preparation

The clotting of blood in specimen collection tubes, their subsequent centrifugation, and the transfer of serum to secondary tubes require time to complete. When performed manually, it has been known to cause delays in the preparation of a specimen for analysis. Consequently, to eliminate the problems associated with specimen preparation, systems are being developed to automate this process. The following developments are noteworthy.

Use of Whole Blood for Analysis

When an assay system has been designed to analyze whole blood samples, specimen preparation time is essentially eliminated. Automated or semiautomated ion-selective electrodes, which measure ion activity in whole blood rather than ion concentration, have been incorporated into automated systems to provide certain test results within minutes of the drawing of a specimen. This approach is now commonly used for assaying electrolytes and some other common analytes. Another approach involves either manual or automated application of whole blood to dry reagent films and visual or instrumental observation of a quantitative change. This approach is exemplified by the Reflotron Plus.

Automation of Specimen Preparation

Several manufacturers have developed fully automated specimen preparation systems. These systems are described later in the chapter.

Specimen Loading and Aspiration

In most situations, the specimen presented to an automated analyzer is serum or plasma. Many state-of-the-art analyzers (e.g., CX/LX series, ADVIA 1650 and 2400, Architect c-8000 series, MODULAR, DIMENSION) directly sample serum from primary collection tubes of various sizes. With such analyzers, the collecting tubes most frequently used contain a separator material that forms a barrier between supernatant and cells (see Chapter 2). Some analyzers also sample from a cup or tube that is filled with serum transferred from the original specimen tube.

Evaporation of specimen from cups or tubes in the loading zone has caused analytical errors as great as 50% over 4 hours.[14] Operationally, all cups or tubes containing solution for analysis should be covered until the time the specimen is to be analyzed. Many manufacturers of automated analyzers provide covers for individual cups or for part or the whole of the loading zone to reduce losses caused by evaporation. Cups may be covered by Parafilm or by caps that are placed over the cups and that have crosscuts to permit ready entry of a specimen probe. A type of antievaporative cover that reduces evaporative losses to less than 0.1%/hr has been described.[16]

Also, specimens may undergo thermal or photo degradation. For example. temperature-labile constituents may undergo degradation if held at ambient temperature. Other constituents that are photolabile, such as bilirubin, are destroyed by ultraviolet light. The adverse effects of ambient temperature may be overcome by holding both specimens and calibrators in a refrigerated loading zone. Photo degradation is reduced by the use of semiopaque specimen containers and by protecting specimens from light both in storage and on the analyzer.

The *loading zone* of an analyzer is the area in which specimens are held in the instrument before they are analyzed. The holding area may be in the form of a circular tray, a rack or series of racks, or a serpentine chain of containers into which individual tubes are inserted. When specimens are not identified automatically, they must be presented to the sampling device in the correct sequence as specified by a loading list. The sampling mechanism determines the exact volume of specimen removed from the specimen. For most analyzers, specimens for a second run may be prepared on a separate tray while one run is already in progress. This permits machine operation and human actions to proceed in parallel for optimal efficiency. In some analyzers, specimens may be added continuously by the operator as the specimens become available. A desirable feature of any automated analyzer is the ability to insert new specimens ahead of specimens already in place in the loading zone. This feature allows the timely analysis of specimens with a high medical prior-

ity when they are received in the clinical laboratory. When specimen identification is machine read, it is easy for the operator to reposition specimens in the loading zone; however, when specimen identification is tied to a loading list, insertion or repositioning of specimens must be accompanied by revision of the loading list.

Transmission of infectious diseases by automated equipment is a concern in clinical laboratories.[81] The method of transmission by equipment is primarily by means of the splatter of serum or blood during the acquisition of specimens from rapidly moving specimen probes.[27] The use of level sensors, which restrict the penetration of sample probes into specimens and provide smoother motion control, greatly reduces splatter. There is no evidence that aerosols, which may be generated by instrument systems, are a source of transmission of infectious diseases.[28,64] However, there is a potential for contamination when the stoppers of primary containers are "popped" to decant serum into specimen cups.[27] To obviate this hazard and the risk of exposure from broken glass, spillage, and stopper disposal, several firms have developed closed-container sampling systems for use in their automated hematology and chemistry analyzers. One such system is used in the Synchron LX PRO chemistry analyzer. On this analyzer, tubes are positioned under the piercing unit where they are clamped and pierced by a blade. Once the cap has been pierced, the sample probe can easily slide through the cap and withdraws an aliquot of specimen. Closed-container sampling is widely used in hematology analyzers.

On-Analyzer Specimen Delivery

The method of specimen delivery within the analyzer is the major difference between continuous-flow and discrete systems. In continuous-flow systems, the specimen is aspirated through the sample probe into a continuous reagent stream, whereas in discrete analyzers, the specimen is aspirated into the sample probe and then delivered through the same orifice into a reaction cup or other container.

Discrete Pipetting

Positive–liquid-displacement pipettes are used for specimen handling in most discrete automated systems. With them, specimens, calibrators, and controls are delivered by a single pipette to the next stage in the analytical process.

A positive-displacement pipette may be designed for one of two operational modes: (1) to dispense only aspirated specimen into the reaction receptacle or (2) to flush out specimen together with diluent. Both systems use a plastic or glass syringe with a plunger whose tip is usually made of Teflon. When a liquid (e.g., diluent or reagent) is used as displacement medium, liquid-displacement pipettes are capable of highly reproducible measurement of serum. However, when air is the displacement medium, viscous fluids can be measured with less accuracy. This inaccuracy becomes apparent when sera containing large amounts of lipids or proteins are pipetted and the analytical results are compared against aqueous calibrators.

Pipettes may be categorized as fixed-, variable-, or selectable-volume (see Chapter 1). Selectable-volume pipettes allow the selection of a limited number of predetermined volumes. In general, pipettes with selectable volumes are used in systems that allow many different applications, whereas fixed-volume pipettes are usually used for specimens and reagents in instruments dedicated to performing only a small variety of tests.

Inaccuracy and imprecision for delivery of specimens from pipettes should not exceed 1%. Similar performance is desired for reagent delivery. The accuracy of the pipetting must be verified periodically, and such checks are a key factor in assessing the quality of instrument performance (see Chapter 14). The accuracy and reproducibility of pipettes in automated instruments are checked in the same way as they are for pipettes in manual systems (see Chapter 1).

On analyzers with several analytical modules (MODULAR, Architect, AU 5400 series), delivery of specimens from the specimen input area to the various modules is accomplished using either built-in conveyor tracks (MODULAR, AU 5400 series) or robotic handling of specimen carriers (Architect) (Figure 11-2). These devices will be discussed in more detail later.

Carryover

Carryover is defined as the unintended transfer of a quantity of analyte or reagent by an analytical system from one specimen reaction into a subsequent one. Because carryover introduces error into the analytical results from the subsequent reaction, it should be minimized. Details for determining the extent of analyte carryover are described in the NCCLS document EP 10-A2, "Preliminary Evaluation of Quantitative Clinical Laboratory Methods; Approved Guideline Second Edition."[58] More elaborate protocols are required to evaluate the extent of reagent carryover.[52] Most

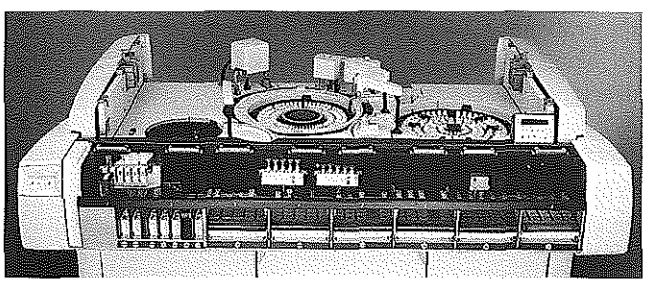

Figure 11-2 A robotic device is used in the Abbott Architect c8000, ci8200, and i2000SR to move racks of specimens from multiple specimen introduction bays located across the front of the analyzer to a bar code reading station *(left)* and to analyzer module sampling areas *(center)*. Covers normally present on this c8000 analyzer have been removed. *(Reproduction of this photograph has been granted with approval of Abbott Laboratories, Inc, all rights reserved by Abbott Laboratories, Inc; www.abbottdiagnostics.com.)*

manufacturers of discrete systems reduce the carryover by setting an adequate flush-to-specimen ratio and by incorporating wash stations for the sample probe. The ratio of flush to specimen may be as much as 4:1 to limit carryover to less than 1%, although recent advances in materials and dispenser velocity control have permitted lower ratios. Appropriate choice of sample probe material, geometry, and surface conditions minimizes imprecision and inaccuracy.

Carryover has been reduced in some systems by flushing the internal and external surfaces of the sample probe with copious amounts of diluent. The outside of the sample probe is wiped in some instruments to prevent transfer of a portion of the previous specimen into the next specimen cup. In discrete systems with disposable reaction vessels and measuring cuvets, carryover is caused by the pipetting system. In instruments with reusable cuvets or flow cells, carryover may arise at every point through which specimens pass sequentially. Disposable sample-probe tips eliminate both the contamination of one specimen by another inside the probe and the carryover of one specimen into the specimen in the next cup. Such an approach is used in the Vitros analyzers, in which a separate disposable tip for each specimen is automatically mounted onto a single, positive-displacement pipette. In these systems, a specimen is partially expelled, and the resultant pendant drop of serum on the tip is touched to the spreading layer of the test slide, where it spreads and subsequently diffuses into the next layer, consisting of a dry reagent matrix. Although the imprecision and inaccuracy of specimen dispensing may be as high as 2%, the volume of fluid that passes to the area exposed to the photometric light beam remains constant, and the resulting final precision is equivalent to 0.2%. Because a new pipette tip is used for each specimen, carryover is totally eliminated.

Reduction of carryover is a more stringent requirement for automated analyzers that perform immunoassays because for some analytes the concentration range in specimens can be as high as 6 decades (as for human chorionic gonadotropin). Some systems use extra steps, such as additional washes, or an additional washing device to reduce carryover to acceptable limits. Because extra steps can reduce overall throughput, additional rinsing functions are initiated (by computer operator selection) only for assays with a large dynamic range.

Reagent Handling and Storage

Most automated systems use liquid reagents stored in plastic or glass containers. For those analyzers in which a working inventory is maintained in the system, the volumes of reagents stored depend on the number of tests to be performed without operator intervention to refill. Whenever possible, manufacturers use single reagents for test procedures, although two or more reagents may be required for some tests. Others (e.g., Vitros and Reflotron Plus) use reagent-impregnated slides and strips, respectively. Still others rely entirely on electrodes to react with specimens (e.g., Bayer RapidLab systems, GEM Premier 3000, Radiometer ABL 700, and i-STAT Portable Clinical Analyzer).

For many analyzers in which specimens are not processed continuously, reagents are stored in laboratory refrigerators and introduced into the instruments as required. In larger systems (e.g., SYNCHRON CX and LX systems, Architect, MODULAR, AND DIMENSION), sections of the reagent storage compartments are maintained at 4 °C to 10 °C. Refrigerated storage for reagents is also provided in most immunoassay systems. Many of the reagents delivered in liquid form by the manufacturers of these systems are stable for 2 to 12 months.

Liquid Reagent Systems

The DIMENSION Clinical Chemistry System, MODULAR, ADVIA 2400, and SYNCHRON series are examples of systems that use liquid reagents. Large volumes of reagents, adequate for operation of the analyzer for hours or days, are stored in the systems. The containers are reservoirs that provide reagents test by test. Reagents with limited stability may be prepared during the analyzer set-up phase and may be stored, during a run, in refrigerated space adjoining the system.

Nonliquid Reagent Systems

No or very little liquid is used in the analytical process on dry reagent systems such as the Vitros and Reflotron Plus. For "color reactions," the Vitros uses a multilayered, 16-mm square slide (Figure 11-3) in which reagents dispersed in emulsions are activated by diffusion of the specimen fluid into the layers. From three to seven layers containing reagents are used for each of the different tests available. The Vitros also uses slides for electrometric assays that incorporate miniature ion-selective electrodes. On these, a reference solution and patient specimen provide fluid that turns the electrodes into electrochemical half-cells (see Chapter 4). Slides of this type that measure sodium, potassium, carbon dioxide, and chloride are currently in use.

The OPUS system has dry reagents impregnated in a coated multilayer film chip encased within a plastic bar coded test module. No external or supplementary reagents are required. A serum or plasma specimen is applied to the test module by the instrument and the fluorescence intensity from the module is measured after an assay-specific time interval.

Systems with Reusable Reagent Capability

Some systems use reagents or antibodies that have been immobilized in a reaction coil or chamber to repetitively carry out a chemical reaction or a separation of an analyte contained in aliquots of successive specimens. Other systems use enzymes immobilized on membranes that are coupled to sensing electrodes. The reaction products are then measured by the sensing device. Only a buffer is required as a diluent and wash solution, and thus the membrane has an extended life of approximately several months. Some

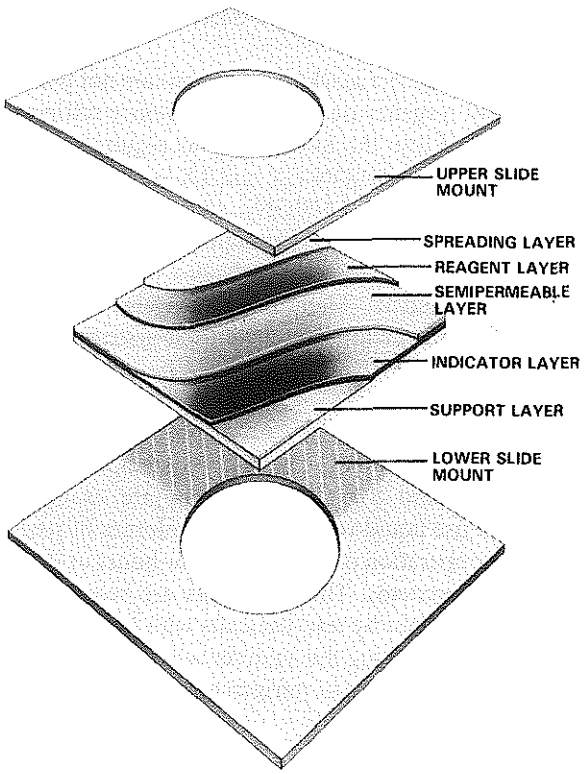

Figure 11-3 A schematic, exploded view of the multilayer dry film reagent used in Vitros analyzers. *(Courtesy Ortho-Clinical Diagnostics.)*

assemblies can be recycled for as many as 7500 tests, resulting in a low cost per test. Application of these systems is found in the 2300 STAT Plus for glucose and lactate assay.

Reagent Identification

Labels on reagent containers include information such as reagent identification, volume of the contents or number of tests for which the contents of the containers can be used, expiration date, and lot number. Provision of much of this information on labels is required by law. Many reagent containers now carry bar codes that contain some or all of this information and the manufacturer is able to retrieve any pertinent information when necessary. Other advantages of using reagent bar codes include: (1) facilitation of inventory management; (2) ability to insert reagent containers in random sequence; (3) ability to automatically dispense a particular volume of liquid reagent. In immunoassay systems, a bar code on a reagent container contains key information about (multiple) calibrators, such as definition of a calibration curve algorithm and values of curve constants that are defined at the time of reagent manufacture. Accompanying calibrator materials provided in their own bar coded tubes at the time of manufacture ensure that calibration functions are properly integrated into the analysis process.

Open Versus Closed Systems

Automated analyzers also are classified as "open" or "closed." In an open analyzer, the operator is able to change the parameters related to an analysis and to prepare "in-house" reagents or use reagents from a variety of suppliers. Such analyzers usually have considerable flexibility and are readily adapted to new methods and analytes. A closed-system analyzer requires the reagent in a unique container or format provided by the manufacturer. In general, liquid reagents for open systems are less expensive than the proprietary components required for closed analyzers. Yet, closed systems have a hidden cost advantage because reconstitution or preparation of the reagents for use does not require a technologist's time. The variability arising from reconstitution of dry reagents can be overcome by the use of predispensed liquid reagents or through the provision of premeasured liquids. The stability of liquid reagents for some open systems is now approaching the longer stability that has characterized many closed systems. Most immunoassay systems are closed, as are most systems that have been developed for POC applications.

Reagent Delivery

Liquid reagents are taken up and delivered to mixing and reaction chambers either by pumps (through tubes) or by positive-displacement syringe devices. In the early continuous-flow systems, such as the SMAC, a peristaltic pump and manifold both delivered fluids and determined the proportion of reagents to specimen. In the SYNCHRON CX series, a stepper motor is used to drive a pump that functions in the same way as the peristaltic pump of the AutoAnalyzer by alternately compressing and releasing a single reagent tube. Syringe devices for both reagent and specimen delivery are common to many automated systems. They are usually positive-displacement devices, and the volumes of reagents they deliver are programmable. Reproducibility of delivered volume is frequently better than ±1% with an accuracy within ±1%. In those analyzers in which more than one reagent is acquired and dispensed by the same syringe, washing or flushing of the probe is essential to prevent reagent carryover that may be deleterious to successive analytical steps in the same assay or to successive and different assays.

Chemical Reaction Phase

As its name implies, the chemical reaction phase occurs when aliquots of specimen and reagents are allowed to chemically react. Concerns related to this operation and the measurement of the reaction are addressed in the design of every automated analyzer. Design issues to be considered include (1) the vessel in which the reaction occurs and the cuvet in which the reaction is monitored, (2) the timing of the reaction(s), (3) the mixing and transport of reactants, and (4) the thermal conditioning of fluids. Separation of bound and unbound fractions is a fifth issue for immunoassay systems, as described in Chapter 9.

Type of Reaction Vessel and Cuvet

In older continuous-flow systems, each specimen passed through the same continuous stream and was subjected to the same analytical reactions as every other specimen and at the same rate. In such systems the reaction occurred in the tube that served as both a flow container and a cuvet.

In discrete systems each specimen in a batch has its own physical and chemical space, separate from every other specimen. Discrete analyzers use (1) individual (disposable or reusable) reaction vessels that are transported through the system after specimen and reagent have been dispensed (Immulite 2000), or (2) a stationary reaction chamber, as in the SYNCHRON CX Series. In some discrete systems, reaction vessels are reused; in others, they are discarded after use. The use of disposable cuvets has simplified automation and eliminated carryover in the cuvets and maintenance of flow cells. Disposable cuvets became possible through the development of superior plastics (notably acrylic and polyvinyl chloride) and manufacturing technology. Large-scale production of cuvets with excellent dimensional tolerances is an essential requirement. The cuvets must be transparent in the spectral range of interest. Disposable components are increasingly used in discrete automated systems.

Reaction vessels are reused in many instruments (e.g., SYNCHRON CX Series, Abbott Architect c8000 series, MODULAR, and the AU 400, AU 640, and AU 5400). The time before reusable cuvet and/or reaction vessels must be replaced depends on their composition (e.g., 1 month for plastic and 2 years for standard glass vessels). Pyrex glass vessels are not replaced unless physically damaged.

The typical cleaning sequence of a reusable cuvet and/or reaction vessel involves aspiration of the reaction mixture out of the cuvet at an in situ wash station. A detergent, alkaline, or acid wash solution is then repeatedly dispensed into and aspirated out of the cuvet. The cuvet is rinsed several times with deionized water and dried by vacuum or pressurized air. Optical clarity is verified automatically in most systems (usually while the cuvets contain the water). If performance is unsatisfactory, the operator is alerted to replace individual cuvets. If the cuvets are not replaced promptly, the system cannot be used for analysis; until they are replaced, the results for the unsatisfactory cuvets will be flagged.

Although the use of reusable cuvets reduces expenditure on consumables and extends walk-away time, it does contribute to instrument complexity and requires that a supply of cleaning liquids be maintained. In Centaur, a supply of individual cuvets is loaded onto the instrument. The number of loaded cuvets ranges from 200 to 1000, permitting walk-away times of approximately 1 to 3 hours.

In the DIMENSION, cuvets of 5-mm path length are manufactured in the instrument by drawing two strips of Surlyn clear plastic around the circumference of a ring mold that contains 100 separate cavities (Figure 11-4). A canister containing sufficient plastic to make 12,000 cuvets is loaded into the instrument. A schematic diagram of the Immulite 2000 analyzer is shown in Figure 11-5. This analyzer is equipped with an automatic tube feeder that accepts polystyrene reaction tubes in bulk, orients them vertically, and delivers them to the bead drop and the pipetting positions. The reaction tube serves as the vessel for all incubations, washes, and signal development. It is discarded automatically after analysis.

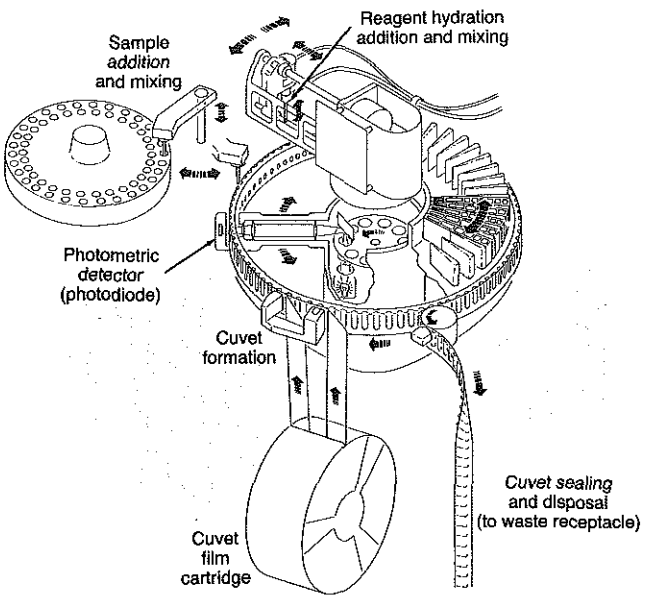

Figure 11-4 Arrangement of key elements of the DIMENSION. Relationships of elements used for in situ cuvet manufacturing are shown. *(Courtesy Dade Behring; www.dadebehring.com.)*

Timing of Reactions

The time allowed for a reaction to occur depends on a variety of factors. In some analyzers reaction time depends on the rate of transport through the system to the measurement station or on timed events of reagent addition (or activation) relative to measurement, or on both. In discrete random-access analyzers specimens and reagents are added to a cuvet in a timed sequence, and absorbance readings are performed at intervals to follow the course of each reaction. Usually, the total read time for a reaction in these systems is constrained to a maximum value defined by the manufacturer but may be programmed for a shorter period.

Mixing of Reactants

Various techniques are used to mix reactants. These include the following: (1) forceful dispensing, (2) magnetic stirring, (3) a rotating paddle, and (4) the use of ultrasonic energy (DIMENSION). Continuous-flow analyzers relied on the tumbling action of the stream flowing through a mixing coil. The dry reagent systems, such as Vitros, Reflotron Plus, Stratus, and OPUS, obviate the necessity for mixing because the serum completely interacts with the dry chemicals as it flows through the matrix of the reaction unit. Regardless of the technique used, mixing is a difficult process to automate.

Thermal Regulation

Thermal regulation requires the establishment of a controlled-temperature environment in close contact with the reaction container and efficient heat transfer from the environment to the reaction mixture. Air baths, water baths, and contact with a heating or cooling plate (e.g., Peltier device) have been used for thermal regulation in commercial analyzers (mostly at 37 °C).

Measurement Approaches

Automated chemistry analyzers have traditionally relied on photometers and spectrophotometers for measurement of absorbance. Alternative approaches now being incorporated into analyzers include reflectance photometry and fluorometry. Immunoassay systems have used fluorescence (IMX), chemiluminescence (Centaur and Immulite), and electrochemiluminescence (ELECSYS) to enhance sensitivity. Ion-selective electrodes and other electrochemical techniques are also widely used. Principles of these measurement techniques have been discussed previously (see Chapter 4). This section reviews the special features and application of the various approaches to automated analysis.

Photometry

The measurement of absorbance requires three basic components: (1) an optical source, (2) a means of spectral isolation, (3) and a detector (see Chapter 3).

Optical Source

The radiant energy sources used in automated systems include tungsten, quartz halogen, deuterium, mercury, and xenon lamps and lasers. In the quartz-halogen lamp, low-pressure halogen vapor (such as iodine or bromine) is enclosed in a fused silica envelope in which a tungsten filament serves as an incandescent light source. The spectrum produced includes wavelengths from approximately 300 to 700 nm.

Spectral Isolation

In automated systems spectral isolation is commonly achieved with interference filters. Such filters are now quite inexpensive, and only a few are necessary in any one instrument, because only a limited number of wavelengths is required for analysis of a large number of absorbing species. Typical interference filters have peak transmission of 30% to

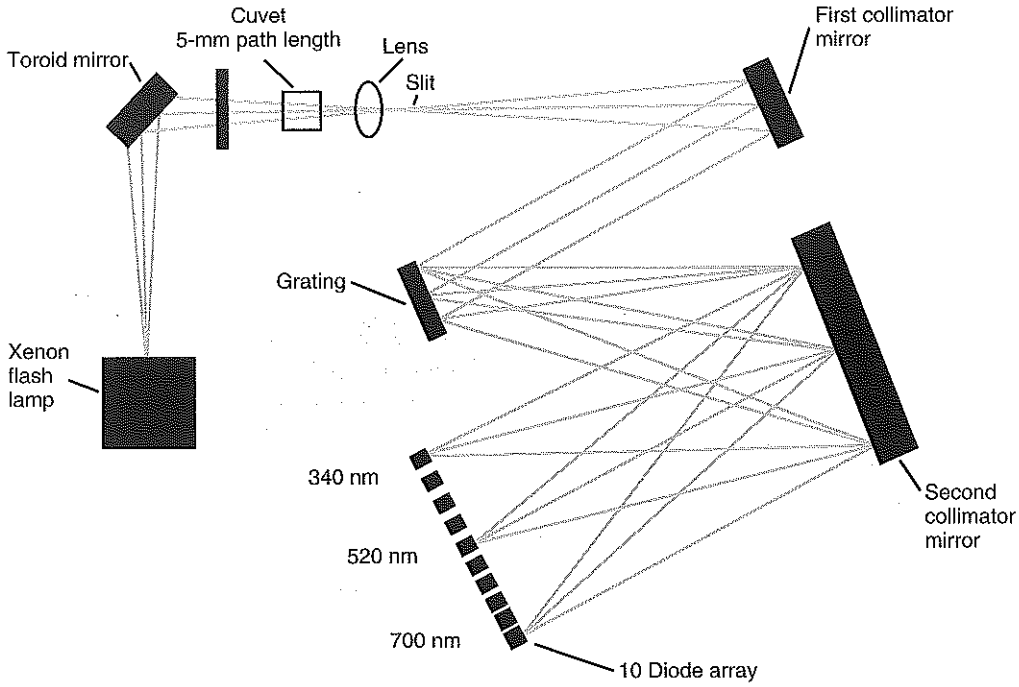

Figure 11-6 Use of a diode array in the SYNCHRON CX7 monochromator reduces requirements for moving parts. For simplicity, ray traces for only three wavelengths are shown. *(Courtesy Beckman Coulter Inc; www.beckmancoulter.com.)*

80% and bandwidths of 5 to 15 nm (see Chapter 3). In several multitest analyzers, filters are mounted in a filter wheel, and the appropriate filter is moved into place under computer control. Monochromators with movable gratings and slits provide a continuous choice of wavelengths. They offer a high amount of flexibility and are especially suited for the development of new assays. However, because relatively few wavelengths are required for analyses in routine analyzers, many manufacturers use a stationary, holographically ruled grating coupled with a stationary photodiode array to isolate the spectrum. These two elements are also coupled with fiberoptic light guides to transfer the passage of light energy through cuvets at locations convenient for mechanization. Use of these passive elements enhances the reliability of a system because no moving parts are required for spectral isolation. Figure 11-6 shows the arrangement of a grating and/or diode array for the SYNCHRON CX Series.

Photometric Detectors

Photodiodes are used as detectors in many automated systems either as individual components or in multiples as an array. Photomultiplier tubes are required in many immunoassay systems to provide adequate sensitivity and fast detector response times for fluorescent and chemiluminescent measurements. Several approaches have been used for the electrooptical integration and packaging in different analyzers. A logarithmic amplifier or microprocessor and/or computer software converts transmittance to absorbance. Low-cost analog-to-digital converters with conversion times of fractions of a millisecond, together with low-cost oscillators with timing accuracy of microseconds, are coupled with high-performance computers to accumulate, store, and process optical signals on a real-time basis. Analyzers that use time sharing of the optical system components tend to be less costly while still providing good performance and reliability. In general an electrooptical package should offer an absorbance range of up to 2.5 absorbance units (A) to permit the extended linearity desirable for some reactions. Its photometric detection limit should be 0.001 A at 1 A and its noise level should not exceed 0.0005 A at 1 A, to ensure precision adequate for measuring kinetic reactions. The spectral range typically required is from 340 to 650 nm, but lower wavelengths may be necessary for some applications. Spectral isolation does not have to be more exact than is necessary for enzyme determinations. For analytes with broad absorbance peaks, interference filters with a bandpass up to 20 nm are satisfactory.

Proper alignment of cuvets with the light path(s) is equally important in automated and manual photometry; stray energy and internal reflections must be kept to acceptable levels. If the light path is not perpendicular to the cuvet, inaccuracy and imprecision may occur, particularly in kinetic analyses. Stray energy is reduced to 0.2% or less by careful design of the wavelength isolation filters or the monochromator to increase rejection of stray light.

Other Forms of Measurement

Several other optical techniques now are widely used in automated systems. Among these techniques are the following:

(1) reflectance photometry, (2) fluorometry, (3) fluorescence polarization, (4) turbidimetry and nephelometry, (5) chemiluminescence and bioluminescence.

Reflectance Photometry

In reflectance photometry, diffuse reflected light is measured. The reflected light results from illumination, with diffused light, of a reaction mixture in a carrier or from the diffusion of light by a reaction mixture in an illuminated carrier. The intensity of the reflected light from the reagent carrier is compared with that reflected from a reference surface. Intensity of reflected light is not linear with concentration of the analyte, and two algorithms are commonly used to linearize the relation of reflectance to concentration.[89] The electrooptical components used in reflectance photometry are essentially the same as those required for absorbance photometry. Reflectance photometry is used primarily in analyzers using dry, unit-dose reagent systems (e.g., Vitros and Reflotron Plus). In the Vitros, equilibrium measurements and kinetic enzyme measurements are monitored by separate reflectometers, each with a permanent reflectance reference. A Clapper-Williams transformation[89] is used to linearize the relation of reflectance to concentration. Adaptive algorithms define the number of points selected for calculation of enzyme activity to provide, in essence, a variable-time analysis as defined by Pardue.[67]

Fluorometry

Fluorescence is the emission of electromagnetic radiation by a species that has absorbed exciting radiation from an outside source. Intensity of emitted (fluorescent) light is directly proportional to the concentration of the excited species (see Chapter 3).

Fluorometry is widely used for automated immunoassay. It is approximately 1000 times more sensitive than comparable absorbance spectrophotometry, but background interference caused by fluorescence of native serum can create a major problem. This interference is minimized by careful design of the filters used for spectral isolation, by the selection of a fluorophore with an emission spectrum distinct from those of interfering compounds, or by using time- or phase-resolved fluorometry (see Chapter 3).

Different optical arrangements are represented in different manufacturers' equipment. Right-angle fluorescence measurement is one of the most common approaches, with emitted light passing through the emission interference filter to a photomultiplier tube.

Front-Surface Reflectance Fluorometry

Front-surface reflectance fluorometry is used in the Stratus CS analyzer, where light passed through a 360-nm filter is reflected from a dichroic mirror onto the front of the reagent tab on which the reaction of the antigen-conjugated enzyme occurs. The light emitted from the front surface of the tab travels back through the dichroic mirror and to a photomultiplier through an interference filter that selects only 450-nm light. Fluorescence intensity is monitored over a 30-second interval, and the rate of fluorescence development is calculated by the microprocessor. The rate of fluorescence change is then compared with the calibration curve stored in the microprocessor, and the test value is computed.

Polarization Fluorometry

In fluorescence polarization, the radiant energy is in the form of polarized light. Measurement is then made of the change in the degree of polarized light emitted by a fluorescent molecule, as described in Chapter 3. Fluorescence polarization is applied in the Abbott TD_x and AxSYM for homogeneous assays of low molecular weight compounds. Radiant energy in the form of polarized light is alternately pulsed vertically and horizontally to impinge on a reaction mixture containing antibody, specimen, and tracer. Free tracer not bound to antibody depolarizes the emitted light, whereas light emitted from a bound tracer is highly polarized. As a result, in this system, polarization is inversely proportional to concentration. The optical system consists of a 50-W projector bulb, an interference filter, a fixed horizontal polarizer, and a photomultiplier tube. An electrically switched liquid crystal is located between the polarizer and the reaction mixture. Absence or presence of voltage on the crystal changes the orientation of the polarized light. Because variability of path length is immaterial to the analytical principle used, inexpensive borosilicate tubes are satisfactorily used for reaction cells. Use of a liquid crystal instead of mechanical devices to modulate the polarized light significantly improves the reliability of the optical system for this sensitive technique.

Turbidimetry and Nephelometry

These two optical techniques are particularly applicable to methods measuring the precipitate formation in antigen antibody reactions (see Chapter 9). Turbidimetry is used in several chemistry immunoassay systems for therapeutic drug monitoring and specific protein assays. Details of turbidimetry and nephelometry are discussed in Chapter 3.

Nephelometers such as the ARRAY, IMAGE, and BN series are widely used for analysis of serum specific proteins (see Chapter 20). These analyzers direct light to a flow cell and detect forward angle light scattering from different sized immune complexes. Reading the light scattering at a forward angle rather than the classical 90° angle is known to increase the sensitivity of nephelometric assays.[78]

Chemiluminescence and Bioluminescence

Chemiluminescence and bioluminescence differ from fluorometry in that the excitation event is caused by a chemical or electrochemical reaction and not by photoillumination (see Chapter 3). The applications of chemiluminescence and bioluminescence have greatly increased with the development of automated instrumentation and several new reagent systems. Because of their attomole to zeptomole

detection limits, chemiluminescence and bioluminescence reactions have been widely used as direct and indicator labels in the development of immunoassays (see Chapter 9). Several of these schemes have been used in new automated immunochemistry analyzers (CENTAUR, Immulite, and ELECSYS).

Electrochemical

A variety of electrochemical methods have been incorporated into automated systems. The most widely used electrochemical approach involves ion-selective electrodes. These electrodes have replaced flame photometry for the determination of sodium and potassium in many analyzers and have lately found direct application in the measurement of other electrolytes and indirect application in the analysis of several other serum constituents. The operating principle of ion-selective electrodes is given in some detail in Chapter 4. The relationship between ion activity and the concentration of ions in the specimens must be established with calibrating solutions, and frequent recalibration must be done to compensate for alterations of electrode response.

Peristaltic pumps are used to move the specimen into chambers containing fixed specimen and reference electrodes. The electrodes must remain in contact with the specimen for a sufficiently long time (from 7 to 45 seconds) to reach steady-state conditions. Response time, therefore, determines throughput of an automated system, and care must be taken to monitor response time and to restore it, when it degrades, by implementing appropriate maintenance procedures. The most common arrangement is to provide electrodes to assay three analytes, typically sodium, potassium, and chloride. Because specimens and calibrators usually flow past a group of electrodes, results for all analytes are reported for most systems. However, ion-selective electrode capability has also been incorporated into automated analyzers as individual channels (SYNCHRON CX series). Integrated three- and four-parameter modules have been incorporated into many small and large random-access systems (e.g., COBAS Integra, MODULAR, Architect c-8000 series, AU 400, AU 640, and AU 5400); this has significantly increased these systems' throughput, because several results are produced in parallel.

Ion-selective electrodes coupled with immobilized enzymes represent an extended application. In such systems, the enzymatic reaction with the analyte involves a product that can be measured electrochemically. An example is the YSI 2300 STAT Plus used to measure glucose in whole blood. In this system, glucose oxidase is immobilized between two membrane layers and catalyzes oxidation of glucose in the fluid, in contact with the membrane, to produce hydrogen peroxide. The hydrogen peroxide in turn is oxidized at a platinum anode. The oxidation results in an electrical current directly proportional to hydrogen peroxide concentration and, therefore, proportional to glucose concentration.

Conductimetry is another electrochemical approach that is used in the SYNCHRON CX series, specifically for the measurement of urea nitrogen. The specimen is introduced into the reaction cup along with a buffered urease solution. With the conversion of urea to ammonium and carbonate ions, the rate of change of conductivity across gold electrodes embedded in the cup is proportional to the concentration of urea nitrogen.

Signal Processing, Data Handling, and Process Control

Computers and computer telecommunications are integral components of the entire analytical and reporting process and control the data input, operation, monitoring, and data reporting functions in automated analyzers. Also, workstations have been used to integrate the operation of one or more laboratory analyzers. Individual analyzers and/or their workstations are electronically interfaced with large central data repositories on laboratory information systems (LIS) and/or laboratory automation systems (LAS) (see Chapter 18).

Computers installed in each analyzer are essential in the acquisition and processing of analytical data. Ancillary internal electronic components include analog-to-digital converters that rapidly (10^{-3} to 10^{-5} seconds) convert analog signals to digital form. Such digitized data are passed to the microprocessor and/or computer that processes the data into useful and meaningful output. Data processing and other computer functions in analyzers depend upon sophisticated software developed by each instrument manufacturer. For example, automation of procedures such as nonisotopic immunoassays and reflectance spectrometry relies on computer algorithms to transform complex, nonlinear standard responses into linear calibration curves. The nature and character of data output can be as varied as output software and hardware allow and as analytical purposes require. Some functions performed by computers incorporated into automated analyzers are listed in Box 11-1.

Other functions of integrated computers include:

1. Computers *command* and *phase* the electromechanical operation of the analyzer, thus ensuring that all functions are performed uniformly, are repeatable, and are in the correct sequence (e.g., transfer of solutions, placement of proper filters, and regulation and change in speed of rotation). Computer control of operational features of automated equipment, calculation of results, and monitoring of operation contribute to the increased reproducibility of results. These combined features, theoretically at least, allow less-skilled operators to operate such systems.
2. Computers *acquire, assess, process,* and *store* operational data from the analyzers. Many computers include built-in test equipment that monitors instrument functions for correct execution and reacts to improper function by recording the site and nature of the malfunction.
3. Computers enable important *communication interactions between the analyzer and the operator.* Alphanumeric displays on monitors or on light-emitting diode arrays provide operator-readable information and signals. The signals may instruct the operator to intervene to replen-

BOX 11-1 Some Signal and Data Processing Functions Performed by Computers of Automated Analyzers

Data Acquisition and Calculation

Acquisition of response signal and signal averaging
Subtraction of blank response
Correction of response of unknown for interferences (e.g., Allen-type corrections)
Linear regression for determining slope
($\Delta A/\Delta t$) of rate reactions; ($\Delta A/\Delta C$) of absorbance/concentration relation; ($\Delta R/\Delta C$) of any response parameter to concentration
Statistics (mean, SD, CV) on patient or control values
Mathematical transformation of nonlinear relations to linear counterpart
Mathematical transformation of results to alternative reporting units

Monitoring

Test for fit of data to linearity criteria for calibration curves or rate reactions
Test of patient result against reference interval criteria
Test of control result against criteria of a quality control standard of performance
Test of moving average of patient results against quality criteria for detecting assay drift

Display

Display of specimens currently being analyzed, tests ordered on each specimen, and expected times of completion
Accumulation of sets of patient results
Collation of results for patient-oriented printout
Provide warning messages to alert operator to instrument malfunction, need for maintenance, or unusual clinical situation
Provide quality control charts for operator review
Provide troubleshooting flowcharts to assist operator

SD, Standard deviation; *CV*, coefficient of variation.

ish reagent supply or to empty waste containers, or they may warn of operating problems that can compromise test results. The message describing the site and type of problem, together with the manufacturer's service manuals, enables quick identification of problems and their prompt correction. Personal computer (PC) operating systems provide detailed and interactive troubleshooting guidance to operators of instruments and visual display of the status of every specimen. Output data tested against preset criteria can be flagged and displayed for the operator's evaluation and assessment. Such information may specify that linearity of a reaction has been exceeded, a reaction is nonlinear, substrate exhaustion has occurred, absorbance of a reagent is too high or too low, or baseline drift is excessive. The computer can also receive commands from the operator through the keyboard or a touch-sensitive screen. These commands may reprogram certain functions of the analyzer (e.g., timing interval for a kinetic reaction and set point of the reaction temperature); enter certain values, such as calibrator concentrations; display stored information in raw or processed form; or define the format of printed output.

4. Integrated computers can in turn *communicate with mainframe computers.* A typical interface implemented in computers is a UART (universal asynchronous receiver and transmitter), which is in turn connected to an RS-232, RS-488, or Ethernet interface to permit interactive communication with other computer systems. The same interface capability permits transmission by modem (modulator-demodulator) over telephone lines. The telephone line may allow the manufacturer's central service department to enhance the ability of the on-site operator to service and repair the analyzer. With a bidirectional interface, it is possible to "download" from the main LIS computer such data as specimen identification, which governs specimen location in the analyzer's loading zone, and to send test results from the analyzer back to the LIS, either in real time or by batch.
5. Computers incorporated into instruments or connected through stand-alone PCs have expanded the capabilities of instrument systems to include those previously available only by connection to the mainframes of LISs. These capabilities include summaries of quality control (production of Shewhart plots), fitting of immunoassay calibration curves using various models (e.g., four parameter log-logistic),[74] and linkage of patient information with specimen identification.

Computer workstations can be used to monitor and integrate the functions of one or more analyzers. Typically, the workstation serves as the point of interaction with the instrument operator, accepts test orders, monitors the testing process, assists with analysis of process quality, and provides facilities for review and verification of test results. The workstation is usually directly interfaced with the LIS host, accepting downloaded test orders, and uploading test results. Most workstations have facilities to display Levy-Jennings quality control charts, to monitor the progress of each test order, and to troubleshoot the analyzers. They may also provide facilities to assist with the review of completed test results. Some workstations have rule-based software, which allows the operator to program rules for autoverification of test results (MODULAR Middleware Software).

INTEGRATED AUTOMATION FOR THE CLINICAL LABORATORY

Significant progress has been made in integrating the individual steps of the analytical process discussed in the previous section into analytical systems. Consequently, advanced analytical systems are now available from multiple vendors for automated chemistry, hematology,[41,69] immunoassay,[18,19,72,91,92]

coagulation,[45,88] microbiology, and nucleic acid testing (see Chapter 37),* which provide efficient and cost-effective operation with a minimum of operator input. Because of increased financial pressures to reduce costs, clinical laboratorians are integrating these analytical systems with "front-end" specimen handling and transport systems to "totally" automate their laboratories and are even considering the automation of previously nonautomated areas.

Some manufacturers have also developed stand-alone "front-end" automation systems, which perform tasks such as sorting, centrifugation, decapping, aliquoting, and labeling of aliquot tubes. These systems may require manual transport of the tubes to the analytical areas, but they have automated steps in specimen processing with acceptable returns on investment for the laboratories that have acquired them. Including the total and modular automation systems described above and these stand-alone systems, total worldwide installations of laboratory automation are estimated at well more than 800 systems as of this writing.

The potential economic benefits of large-scale automation of the laboratory are enormous. Carried to the fullest extent, large-scale automation of the laboratory includes an automated specimen processing area where the operations of specimen identification, labeling, scheduling, centrifugation, and sorting of specimens are initiated. After specimen processing, automated specimen conveyor devices transport the sorted specimens to the appropriate workstations in the laboratory, where they are analyzed without human intervention. Rule-based expert system software assists with the review of laboratory results by automatically releasing results that have no associated problems, but drawing any problematic results to the attention of trained medical technologists. All specimens are cataloged after analysis and stored in a central storage facility, available for automated retrieval if necessary. As pointed out previously, particularly important aspects of large-scale automation projects are the approaches used to process and transport specimens and the overall integration of the automated components into a smoothly functioning whole.

We begin this section with discussions of the roles that workstations, instrument clusters, and workcells have in laboratory automation, followed by discussions of specimen transportation, automated specimen processing, automated specimen sorting, and automated specimen storage and retrieval subsystems.

Workstations

The task of integrating laboratory automation begins with the laboratory workstation.[12,56] In general, a clinical laboratory workstation is usually devoted to a defined task (e.g., performing chemistry profiles, complete blood counts, hormone testing, polymerase chain reaction testing, and urinalysis) and contains appropriate laboratory instrumentation to carry out that task. Frequently, the workstation in the modern laboratory is defined in terms of the automated analyzer that is being used. Current laboratory instruments and systems are highly developed for stand-alone operation and fit into the workstation concept. Movement of specimens into and out of the workstation is accomplished by manual transport, and the instrument operator activities are largely independent of those at other workstations. On a typical instrument, the instrument operator follows a manufacturer-recommended sequence of calibration, quality control, and daily maintenance activities, and uses the instrument's front-panel functions to introduce specimens for analysis. If the analyzer has a bidirectional interface with a laboratory information system (LIS; see Chapter 18) and bar code reading capabilities, information regarding what assays to run on each specimen is downloaded from the LIS, and the instrument operator simply loads bar code–labeled specimens into the specimen input area. The built-in diagnostics supplied in most modern analyzers (e.g., to detect malfunctions during the assay process, to track usage of reagents, and to notify the operator of out-of-range results) provide enough "intelligence" in the analyzer that the operator is able to "walk away" from the instrument for short periods, confident of its reliable operation. Nevertheless, the operator needs to attend periodically to instrument operation, replenishing reagents, evaluating instrument diagnostic messages, and introducing new specimens into the specimen input tray.

Instrument Clusters

To reduce labor costs, instrument manufacturers are developing approaches that will allow a single technologist to simultaneously control and monitor the functions of several instruments. Initially, such workstations have been configured with *clusters* of identical instruments, such as Vitros or Architect i2000 analyzers (Figure 11-7). Each cluster of analyzers has its own central control module (typically a PC) with software designed to assist the technologist in monitoring the functions of each analyzer and to aid in the review of laboratory results generated by the cluster. Access to the many front-panel functions of each analyzer is provided by the interface between the analyzer and the central control module. More advanced instrument clusters incorporate both chemistry and immunoassay analyzers (MODULAR and Architect CI series). The development of instrument clusters is possible in large part because the manufacturers have designed sufficient diagnostic capacities into their instruments to enable the autonomous "walk-away" mode of operation discussed previously. Thus the technologist can load specimens onto each instrument in the cluster and then monitor subsequent instrument operation and review the results at the central workstation. By incorporating the activities of what would be *several* workstations in most current laboratories into a *single* integrated workstation, this approach shows promise in saving laboratory manpower.

*References 20, 22, 34, 51, 65, 68, 92.

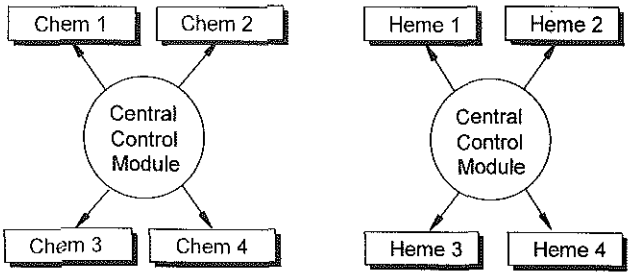

Figure 11-7 Workstations with clusters of like instruments (e.g., chemistry analyzers, Chem 1 through Chem 4, or hematology analyzers, Heme 1 through Heme 4) enable one technologist to operate and monitor the functions of several analyzers simultaneously. The central control module is usually provided by the manufacturer of the analyzers in each cluster. *(From Boyd JC, Felder RA, Savory J. Robotics and the changing face of the clinical laboratory. Clin Chem 1996; 42:1901-10.)*

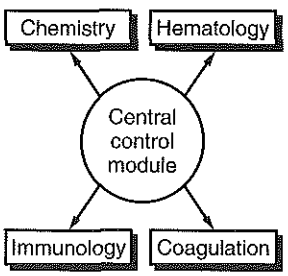

Figure 11-8 A workstation configured with a cluster of unlike instruments theoretically allows one technologist to operate and monitor the functions of several unlike analyzers. The software provided for the central control module is vitally important for successful implementation of such a configuration. Central control modules for this type of instrument cluster are under development by some LIS vendors and independent system integrators. *(From Boyd JC, Felder RA, Savory J. Robotics and the changing face of the clinical laboratory. Clin Chem 1996; 42:1901-10.)*

A possible extension of this concept is the development of clusters of unlike instruments (Figure 11-8) that cross traditional laboratory disciplines. When it is possible for a single technologist to monitor a workstation performing simultaneous testing from several disciplines, further reduction of laboratory manpower is envisioned. Bush[17] used a "chematology laboratory" to describe his joining of routine chemistry and hematology into a single instrument cluster in his laboratory. Interfaces between laboratory instruments in a cluster and the central control module are critical components of such a cluster. Standard interface design that would allow uniform communication of instructions to instruments from the central control module, and reporting of status information and laboratory results from the instruments to the central control module would facilitate the development of hybrid instrument clusters; however, current instrument interface standards do not yet allow for standardized transmission of instrument control instructions,

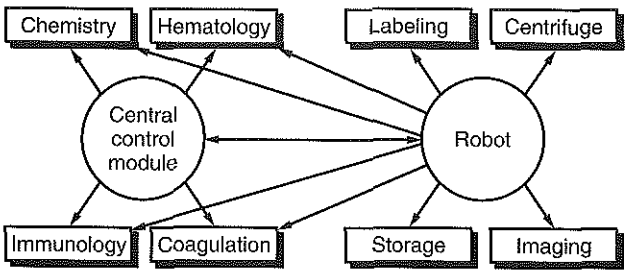

Figure 11-9 Example of a workstation configured with a cluster of unlike instruments and robotic specimen processing that could be useful in remote automated laboratories or in small outpatient laboratories. *(From Boyd JC, Felder RA, Savory J. Robotics and the changing face of the clinical laboratory. Clin Chem 1996; 42:1901-10.)*

and most laboratory instruments are not designed to accept commands from a remote computer.[53] Thus enhanced communication between different types of laboratory automation is necessary if this extended instrument cluster concept is to be successful (see later, under Development of Standards for Laboratory Automation).

Workcells

Another extension of the instrument cluster concept is to add robotic specimen handling and preparation (Figure 11-9).[54] The robot is used to carry out various specimen preparation steps, including checks of specimen adequacy, centrifugation, aliquoting, labeling, and specimen storage after analysis. The robot is then responsible for introducing specimens into the appropriate analyzer, allowing the technologist to assume a primarily monitoring role. An interface between the central control module and the robot controller (or combining these functions on a single computer) allows the activities of the robotic cluster to be fully coordinated. The ability to carry out serial centrifugation of specimens as described by Godolphin et al[36] and others[25,26] would be ideal at a workstation because it would prevent the time delays introduced by batching of specimens in traditional centrifugation. As is mentioned in a section below on stand-alone specimen processing systems, several vendors are now marketing workcells that combine specimen processing with analytical testing. The Ortho enGen 1 system interfaces the enGen processing system with a Vitros 950AT analyzer. The Olympus OLA4000 workcell integrates an automated specimen processing system with up to two AU series analyzers depending on desired capacity.

Automated Specimen Transport

Different approaches have been developed to transport specimens within the laboratory, including mobile robots, conveyor belts, and robotic arms.

Mobile Robots Versus Conveyor Belts

Mobile robots and conveyor belts have been used in the laboratory as aids to transport specimens from one clinical lab-

oratory workstation to another. *Conveyor belt technology* has been applied successfully in industry for carefully defined transportation requirements. However, the difficulty this technology has in handling the large variety of specimen containers found in the clinical laboratory (ranging from microspecimen containers to large urine collection containers) is a disadvantage. To increase the variety of types of specimen containers that can be carried on a conveyor belt system, specimens are placed into specially designed carriers that fit on the conveyor belt line. Known as "pucks" or "racks" (depending on whether they carry individual specimens or groups of specimens), the carriers have receptacles for variously sized tubes. The Beckman Coulter Power Processor system carries specimens individually in disk-shaped pucks, whereas the Roche Diagnostics-Hitachi system carries specimens in racks that hold five tubes. Both of these systems have limitations on the tube sizes they can accommodate. Although some conveyor belt systems are custom manufactured for a facility (Simpliflex), others (Beckman Coulter, Roche Diagnostics-Hitachi, and Flexlink) are sold in modular form, including straight and curved pieces of track of varying lengths, crossover modules, and gating modules that can be assembled in various configurations to match a given laboratory geometry.

Elevator modules are available for some systems that allow pucks or racks to be moved up to ceiling height or under the floor for transport. Elevator modules vary in their ability to keep the specimen in an upright position, an important consideration if the tubes are being transported in an uncapped state. Eggert et al[24] have developed a unique overhead conveyor system for delivery of specimens from a central receiving area to appropriate laboratory workstations. Diamond et al[21] have described the use of conveyor belt technology in carrying out automated analyses in the hematology laboratory. Rothe et al[75] have provided estimates of the cost savings that may be achieved by such an approach.

Transfer of specimens from the conveyor belt to the laboratory workstation has been implemented in various ways. For example, many manufacturers have equipped their laboratory instruments with devices to obtain specimens from conveyor belt systems. The Vitros 950 AT and 250 AT analyzers, Dade Behring Dimension RxL, Abbott Architect, and Bayer ADVIA Centaur are examples of analyzers that can sample directly from open tubes on a conveyor belt track that has been physically attached to the back or side of the analyzer. Diagnostic Products Corp. has a specimen management system (SMS) that can be linked to a single Immulite 2000 or that can form an immunoassay workcell by linking with two Immulite 2000 analyzers. The SMS uses a robot arm to transfer specimens back and forth between racks of specimens that have been loaded into the SMS and the analyzer carousels. Thus racks of specimens have merely to be loaded into the SMS, which then manages the process of loading and unloading both analyzers. The SMS can also be attached to a conveyor system from which the same robot arm can transfer specimens from the conveyor directly into an Immulite 2000 or into empty racks in the immunoassay workcell. The SMS can also return specimens to the conveyor after the test results have been verified, provided there is an empty carrier in the proper position on the conveyor.

In contrast with the limited ability to reconfigure conveyor belt systems and their limited ability to handle different sized specimen containers, *mobile robots* are easily adapted to carry various sizes and shapes of specimen containers, and can be reprogrammed to travel to new (and distant) locations with changes in laboratory geometry. Limitations of mobile robots include their requirement of having to batch specimens, and their difficulty in interfacing mechanically with laboratory analyzers so that specimens are introduced directly from the mobile robot onto the analyzer. In many situations, laboratory personnel are still required to place specimens onto or remove specimens from the mobile robot at each stopping place. Mobile robots have been used to return conveyor belt specimen carrier racks to the central dispatch area and for transport of specimens within and outside the laboratory. In the latter application, mobile robots may be a useful alternative to pneumatic tube delivery systems.

Mobile robots have been equipped with simple (Robocart) or sophisticated (Helpmate) guidance systems. Robots with simple guidance systems follow a predetermined route (such as a line on the floor) to reach their destination, whereas robots with more sophisticated guidance systems are expected to navigate independently through a facility. The costs of the technology, not unexpectedly, vary directly with the degree of sophistication. Sophisticated guidance systems require more built-in sensors to provide enough information about the robot's outside environment to enable independent navigation. A review of commercially available mobile robots has been published.[32]

Robot Arms

The early applications of programmable robotic arms in the clinical laboratory have been reviewed.[30,31] Robotic arms were first used by the pharmaceutical industry to conduct drug dosage studies, and then by clinical laboratories to carry out highly complex clinical assays. Three types of robotic devices are commercially available: cartesian, cylindrical, and articulating (Figure 11-10). Robots, by virtue of their operational flexibility, enable systems to be reconfigured rapidly for new and varying protocols. This enhances versatility and safety, improves precision and productivity, and reduces errors caused by human mismatching of specimen identity. However, misprogramming of the systems can result in repetitive errors with potentially grave medical and legal consequences; thus great care is required to ensure that such errors do not occur.

Cartesian systems are the most common form of robotics in use in laboratories at present. Embodied in programmable pipetting stations, they provide flexible pipetting routines to suit varied protocols. They have been applied

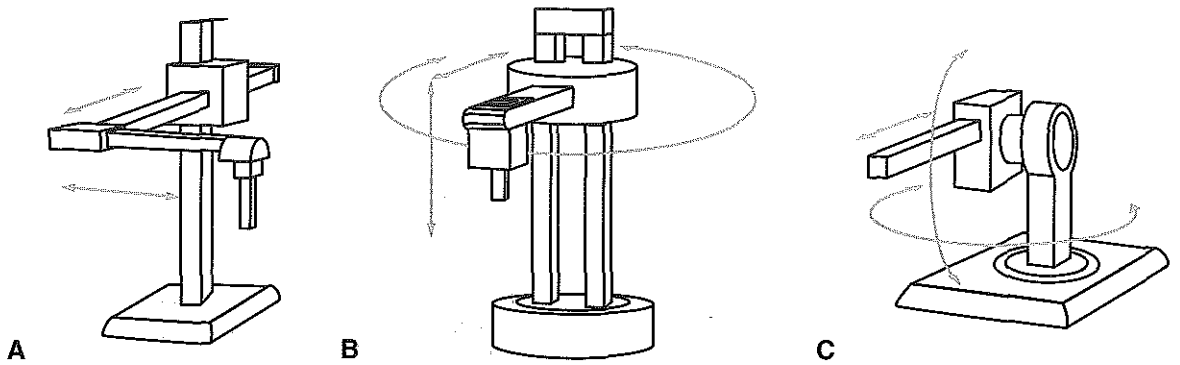

Figure 11-10 Three basic configurations of robotic devices that have application in the clinical laboratory. **A,** Cartesian. **B,** Cylindrical. **C,** Articulating (polar) or jointed. *(Courtesy the Journal of the International Federation of Clinical Chemistry 1992; 4:175.)*

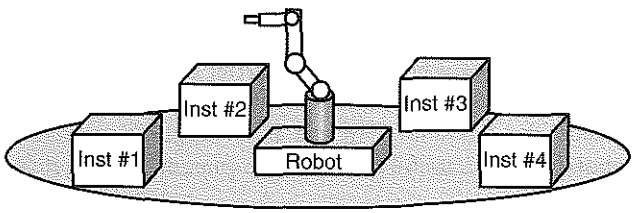

Figure 11-11 Radial arrangement of peripheral equipment around a centrally located robot. Such a workstation requires a circular work space in the laboratory with easy access from all sides. *(From Boyd JC, Felder RA, Savory J. Robotics and the changing face of the clinical laboratory. Clin Chem 1996; 42:1901-10.)*

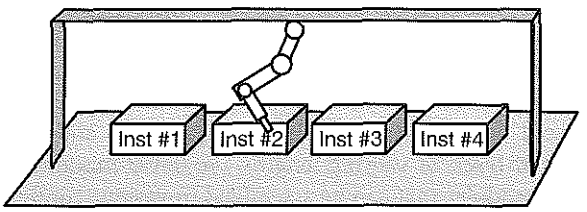

Figure 11-12 Use of a robot on a linear track allows placement of peripheral equipment with which the robot interacts on a rectangular table. This workstation configuration uses a more conventional rectangular space that can be set along a wall. *(From Boyd JC, Felder RA, Savory J. Robotics and the changing face of the clinical laboratory. Clin Chem 1996; 42:1901-10.)*

most often to automating heterogeneous assays. Examples of cartesian systems include Microlab 2000 and 2200, Plato 3000 series, and Tecan. The Integra incorporates a cartesian robot for carrying out all pipetting activities on the analyzer.

Robot arms have varying configurations and degrees of freedom of movement.[30] Two types of arms have been used in clinical laboratories: (1) cylindrical robot arms with interchangeable hands (Zymate); and (2) fully articulated robot arms with wrist and elbow joints (Thermo CRS). When the arm is attached to a stationary base, its range of motion is constrained (Figure 11-11) to a hemispherical or cylindrical space around the robot base (depending on the type of robot). This limit on the range of motion restricts the positions of devices with which the robot interacts to a radial pattern around the robot base. Some robot manufacturers have mounted their robot arms on mobile bases attached to a track (Figure 11-12). The track extends the range of motion of the robot so that instruments and devices with which the robot interacts can be arrayed linearly along a table or bench.

The reproducibility of robot arm motions is in general very good, having a standard deviation of less than 1 mm for positional repeatability.[79] Although high-level programming languages are available for robot arms and are relatively easy to use, it has been difficult to find laboratory personnel who understand the existing robot control programs and can make appropriate modifications to the programs when improvements are made to the assay protocol or when the assay protocol changes with the acquisition of newer analytical devices.

Few of the originally described robot arm applications in North American clinical laboratories remain operational today because there are too few trained personnel to maintain the software. Applications of robot arms in the Kochi Medical School (Nankoku, Japan), by contrast, appear to have enjoyed greater longevity because the technologists working in that laboratory have had appropriate training in programming and maintaining these applications. Because the applications of robotic arms in pharmaceutical laboratories have been highly repetitive procedures with relatively low complexity, competent systems integrators have been able to profitably produce and maintain working pharmaceutical robotic testing systems. Systems integrators have not been eager to develop customized medical robotics systems in U.S. clinical laboratories because of issues related to compliance with Food and Drug Administration regulations for medical devices.

Automated Specimen Processing

Although the manual operations carried out in a specimen processing area have the outward appearance of being

simple, considerable complexity underlies these operations. Consequently, specimen processing has been one of the most difficult areas of the clinical laboratory to automate.

Automating the specimen processing area has been approached in various ways using both integrated and modular approaches, which are discussed below. Each specimen passing through a specimen processing area has to undergo a series of operations, beginning with (1) receiving the specimen, (2) inspecting it for appropriateness (labeling, container type, and quantity of specimen), (3) logging onto the laboratory information system, (4) labeling with an accession number, and (5) separating urgent and stat specimens from routine specimens. Also, specimens must be sorted for centrifugation, aliquoting, or otherwise prepared for the appropriate laboratory station. Centrifugation must be performed for the appropriate period of time usually based upon matrix and assays to be performed, and each centrifuged specimen must be inspected for appropriate quality (e.g., noting presence of hemolysis, lipemia, and icterus) and sorted according to its workstation destination. Adding to the difficulty of programming an automated system is the fact that typical clinical laboratories receive diverse specimen containers with all types of specimens to be evaluated (ranging from blood to hair) and have a test repertoire exceeding 2000 different tests.

Stand-Alone Specimen Processing Systems

Several manufacturers (AI Scientific, Aloka, Olympus [Figure 11-13], Ortho-Clinical Diagnostics, and Tecan [Figure 11-14]) offer stand-alone or independent specimen processing systems that automate various tasks but do not provide conveyors for transporting specimens between subsystems. All of these systems place processed specimens into racks that must be transported manually to the testing areas, with some exceptions. The system from Olympus can also be directly interfaced to Olympus analyzers and the systems from Ortho-Clinical Diagnostics (which is made by Thermo Electron Corporation) can be directly interfaced to analyzers from different vendors. Some of these stand-alone systems are about the size of a large automated analyzer and others may be a little larger. They may be a good choice for laboratories with daily workloads of 500 to 2500 specimens, laboratories with space limitations, or laboratories that desire an upgrade path and ease of use with different analyzers from different vendors. Some laboratories may choose to use multiples of a stand-alone specimen processing system to automate archiving and preanalytical specimen processing.

Each of these systems has the following capabilities: (1) receiving incoming specimens, (2) sorting, (3) decapping, (4) aliquoting, and (5) bar coded labeling of aliquot specimen containers. All can be interfaced to the laboratory's LIS. In addition, the Ortho-Clinical Diagnostics, Tecan, and one of the two Olympus systems include automated centrifugation. Several of the systems sort into instrument-specific racks for analyzers from a number of different vendors. In addition to sorting for particular analyzers or laboratory sections, some users apply these systems for aliquoting and sorting their reference or "send-out" testing, saving considerable time in locating the original specimens after testing in their own laboratory. The AI Scientific and Aloka systems are not yet marketed in the United States.

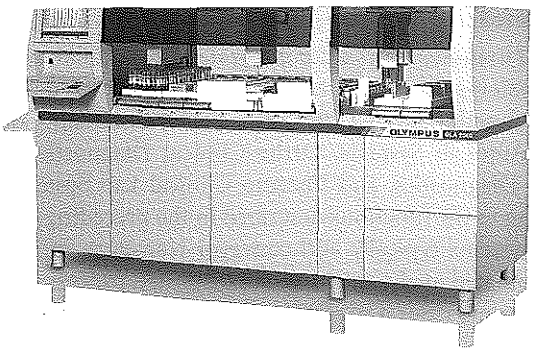

Figure 11-13 The Olympus OLA-2500 Decapper/Sorter/Archiver/Aliquotter has a maximum sorting throughput of 800 tubes per hour and a typical aliquoting throughput of 600 tubes per hour. Olympus also has an OLA-4000 system, which includes centrifugation and can be integrated with up to two Olympus AU-series automated analyzers. *(Courtesy Olympus America, Inc; www.olympusamerica.com.)*

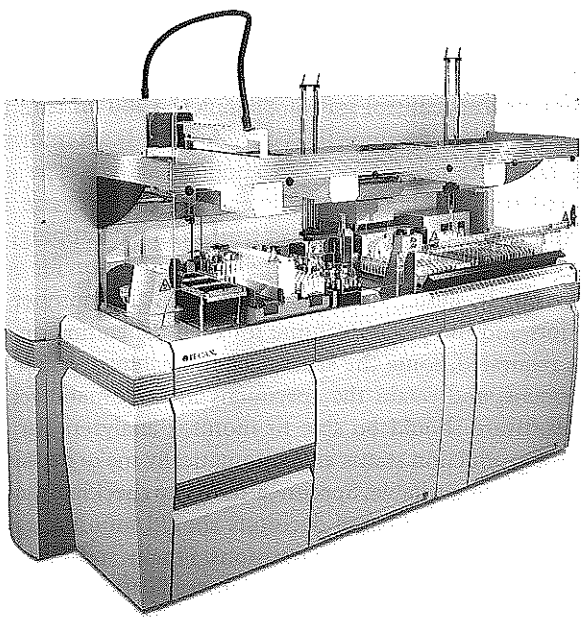

Figure 11-14 The Tecan Genesis FE-500 Workcell performs presorting, specimen volume inspection, centrifugation, decapping, aliquoting, and destination sorting into racks specific to a number of different analyzers with a throughput of up to 500 primary tubes per hour. *(Courtesy Tecan, US, Inc; www.tecan-us.com.)*

Integrated and Modular Automation Systems

Several manufacturers offer integrated or modular automation systems for specimen processing that includes additional functionality (A&T Corp., Bayer, Beckman Coulter, MDS AutoLab Systems, Ortho-Clinical Diagnostics, PVT, Roche Diagnostics, and Thermo Clinical Lab Systems). In addition to the functions described in the preceding section, these systems typically add conveyor transport, interfacing to automated analyzers, more sophisticated process control, and in some cases a specimen storage and retrieval system. All of the systems are of modular design, allowing the customer to choose the functions (e.g., centrifugation, sorting, aliquoting, etc.) to be included. Some of the systems use an open design, which permits interfaces to analyzers from a variety of vendors, whereas other systems are of a closed design and can only be interfaced to the vendor's own or a limited number of analyzers. It should be noted that closed systems typically do not have process control software that is independent of the instruments or system, but rather the automation process control is integrated to work with the vendor's analyzers. This design may make it difficult for the laboratory to change analyzers to another vendor in the future.

To achieve maximum effectiveness of an automation system, process control software should be able to read the specimen's identification (ID) bar code and obtain information from the laboratory's LIS about specimen type and ordered tests. It should then determine the processes the specimen requires—such as centrifugation, decapping, or aliquoting—and the exact route or course of action for each specimen. It should be able to calculate the number of aliquots and the proper volume for each depending on the tests requested, route the specimens to analyzers, recap the specimens, and retain the specimens for automatic recall. The software should be able to monitor analyzers for in-control production status and automatically make decisions if a test is not available. Specimen integrity checking should be automatic; rules-based decisions should monitor specimen quality and make these decisions. Finally, most process control software should include "autoverification," which is validation of analyzer results by making rules-based decisions that flag exceptions for technologist review, and "autoretrieval" of specimens for repeat, reflex, and dilution testing.

Although most of these systems are restricted to handling specific types of specimen containers, they are capable of processing much of the daily workload of a laboratory and have been installed in more than 500 laboratories around the world. Although a few laboratories with daily workloads as low as 600 to 800 specimens tubes have justified these systems because of a shortage of technical help, normally these systems are designed for laboratories with workloads of 1000 to 10,000 specimens per day. In addition to process control software and the ability to be interfaced to the laboratory's LIS, each of these systems incorporates some or all of the following components:

1. *Specimen input area:* A holding area where bar code–labeled specimens are introduced into the system.
2. *Bar code reading stations:* Multiple bar code readers are placed at critical locations in the processing system to track specimens and provide information for their proper routing to various stations in the processing system.
3. *Transport system:* Segments of a conveyor belt line that move specimens to the appropriate location.
4. *High-level sorting or routing device:* A device that separates specimens by type (such as by tube height) or by order code and passes them to the transport system or to a racking system. High-level sorting is often used to separate specimens that require centrifugation, or other processing steps from specimens that do not, or to route specimens into completely different pathways within the total automation system.
5. *Automated centrifuge:* An area of the specimen processor in which specimens requiring centrifugation are removed from the conveyor belt, introduced into a centrifuge that is automatically balanced, centrifuged (either refrigerated or at room temperature), and then removed from the centrifuge and placed back on the transport system.
6. *Level detection and evaluation of specimen adequacy (specimen integrity):* An area in which sensors are used to evaluate the volume of specimen in each specimen container and to look for the presence of hemolysis, lipemia, or icterus.
7. *Decapping station:* An area or device in the automated system in which specimen caps or stoppers are automatically removed and discarded into a waste container.
8. *Recapping station:* An area or device in the automated system in which specimen tubes are automatically recapped with new stoppers or covered with an air-tight closure.
9. *Aliquoter:* Aspirates appropriately sized aliquots from each original specimen container and places them into bar coded secondary specimen containers for sorting and transport to multiple analytical workstations.
10. *Interface to automated analyzer:* a direct physical connection to an automated analyzer that permits the analyzer's sampling probe to aspirate directly from an open specimen container while the container is still on the conveyor, or that may robotically lift the container from the conveyor and place it in the analyzer. Some automation systems only interface to their own brand of analyzers or to a limited number of systems, whereas other automation systems use a so-called open design that complies with the NCCLS standards and permits interfaces to a variety of automated analyzers.
11. *Sorter:* an automated sorting system for sorting of specimens not going to a conveyor-interfaced analyzer or workstation. Such a sorter typically sorts into 30 to 100 different sort groups in racks or carriers. In some systems the racks can be specific to certain analyzers for convenience.

12. *Take-out stations:* Temporary storage areas for specimens before or after analysis. The take-out station may be the same as the sorter described above where specimens are sorted for manual delivery. However, it may also serve as a holding area (stockyard) for specimens awaiting autoverification of results in case a repeat test is required.
13. *Storage and retrieval system.* This unit may serve the same function as the take-out station or stockyard—that of holding specimens after analysis in case a specimen is necessary for a repeat test, but it has one major difference. These units are typically refrigerated and hold many more specimens (several thousand) than the typical take-out station or stockyard. Depending on daily workloads, the laboratory may be able to retain one week's worth of specimens for possible repeat or additional tests. Specimen containers are loaded and retrieved robotically.

Brief descriptions of the integrated (modular) automation systems appear in the following sections.

A&T Corporation

The A&T CliniLog system includes specimen input, bar code reading, high-level sorting or routing, conveyor transporting, centrifugation, decapping, aliquoting, bar code labeling of racks of aliquot specimens, interfacing to chemistry and immunochemistry analyzers, and a terminal stocker. Specimens can be transported in racks of 5 or 10 specimen containers. A&T has approximately 60 installations in hospitals and laboratories in Asian countries and has recently begun marketing in the United States. A&T participates in the Open LA21 Project, an effort involving 10 different companies to develop a modular automation system by following the NCCLS and Japanese standards for laboratory automation. This system allows single specimen transport and has all of the 13 functions listed above.

Bayer Diagnostics

The Bayer Diagnostics ADVIA LabCell and ADVIA WorkCell Modular Automation Systems use circular single tube carriers capable of transporting various size primary tubes and a unique dual conveyor design that allows specimen tubes to bypass intermediate stations to quickly reach other stations in the total system. The capabilities of these systems include specimen input, bar code reading, high-level sorting and/or routing, conveyor transporting, centrifugation, decapping, interfacing to Bayer's chemistry, immunochemistry, hematology, urine analyzers, a take-out station, and archiving capabilities for finding specimens postanalysis. An automated aliquoter is under development. Bayer's ADVIA CentraLink provides a single LIS interface for all automation and analyzers and serves as the consolidated data and quality control (QC) manager. There are more than 73 U.S. installations worldwide with approximately half in the United States as of this writing.

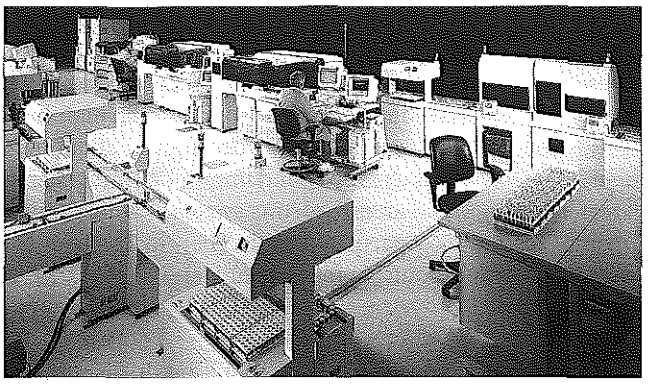

Figure 11-15 Beckman Coulter Power Processor System. This photograph is of an actual system installed in a large hospital laboratory. This system design includes modules for preanalytical processing and analyzers. *(Courtesy Beckman Coulter Inc; www.beckmancoulter.com.)*

Beckman Coulter

The Beckman Coulter Power Processor (formerly the Coulter IDS System) transports specimens in disk-shaped carriers known as "pucks" (Figure 11-15). The system includes specimen input, sorting, centrifugation, decapping, specimen volume detection, aliquoting, bar code labeling of aliquot specimens, interfaces to Synchron LX and other vendors' analyzers, recapping, a downstream sorter or stockyard, and a refrigerated storage system for finished specimens. The pucks cannot be removed from the track. Therefore devices such as the centrifuge or analyzers into which tubes are transferred have an adjacent area of track in which empty pucks are queued to await the return of each tube to a puck. Beckman Coulter has approximately 180 installations of the Power Processor or the IDS system worldwide and offers a full line of systems from entry level to very complex custom systems.

MDS AutoLab

MDS AutoLab generally only builds automation systems in laboratories that are wholly or partly owned by MDS. However, one very large reference laboratory not owned by MDS does have a highly successful AutoLab system, which has been described in publications.[42,43] There are a total of seven MDS installations in the United States and Canada. The AutoLab system uses unique transport carriers that transport individual specimens, but which can be removed from the track and snapped together into blocks of carriers that resemble tube racks for tubes. Capabilities of the MDS AutoLab systems include high-speed specimen input, conveyor transport, decapping, interfacing to chemistry and immunochemistry analyzers from different vendors, recapping, and high-speed sorting.

Ortho-Clinical Diagnostics

Ortho's automation systems are designed and built by Thermo Electron Corp. This arrangement gives customers

an option of acquiring the automation system and Ortho's analyzers as a package and having a single source for service. These systems have the following functionalities: specimen input, bar code reading, transporting system, high-level sorting or routing, centrifugation, decapping, aliquoting, interfacing to various chemistry and immunochemistry analyzers, recapping, and an exit-sorting system. Ortho-Clinical Diagnostics has also partnered with Thermo Electron for automated systems outside the United States.

PVT

The capabilities available with PVT's modular automation include specimen input, sorting, automated centrifugation, specimen integrity inspection, decapping, aliquoting, bar code labeling of aliquot specimens, recapping, specimen distribution with cap piercing, and a take-out and sorting station. All PVT systems can accommodate all common container sizes and all specimen types. PVT uses the Hitachi 5-position rack for their single-task modules. The multi-task workstations from the RSD 800 series work with racks from almost any vendor. Their specimen integrity system measures specimen volume and detects clots, hemolysis, icterus, and lipemia. Each PVT module can be purchased independently to meet specific laboratory requirements. PVT has more than 300 installations in Europe and more than 20 installations in the United States.

Roche Diagnostics

Roche Diagnostics' MODULAR *PREANALYTICS* (MPA *Plus*) automation system is manufactured by Hitachi and is based on the Hitachi 5-tube rack. The capabilities of this system include specimen input, centrifugation, decapping, aliquoting, bar code labeling of aliquot tubes, specimen integrity checking, interfacing to Roche and/or Hitachi MODULAR analyzers, recapping, sorting, and a take-out station. Components can be purchased in a customized fashion to meet the requirements of individual laboratories. Roche Diagnostics and Hitachi have approximately 120 installations worldwide.

Thermo Electron Corporation

Thermo Clinical Labsystem's TC Automation system uses single specimen carriers, which can accommodate a variety of container sizes and multiple tube carriers. Their system can also accommodate racks of different sizes or types in their exit sorting system. The system's capabilities include specimen input, bar code reading, high-level sorting or routing, centrifugation, decapping, aliquoting, bar code labeling of aliquot specimens, interfaces to various chemistry and immunochemistry analyzers, and an exit-sorting system. To date, Thermo Electron has 14 installations, which have all been in Europe, but they are now marketing in the United States.

Automated Specimen Sorting

Several approaches to automated sorting of specimens have been taken including (1) use of a conveyor belt, (2) automated sorting into racks, and (3) stand-alone sorters. Selecting the correct one of these approaches is an extremely important determinant of the overall scheme of automation in any particular laboratory.

Integration with a Conveyor System

Three types of conveyor sorting systems have been used. One type uses a continuous loop in which all specimens follow the loop and go past each workstation or analyzer. Specimens are either sampled directly by the analytical instrument while on the conveyor, or a robot attached to the workstation removes selected specimens from the conveyor for analysis (Figure 11-16). This approach has the advantage that specimen aliquoting is not required because specimens pass by all workstations at which tests are performed. However, the continuous loop also has some drawbacks in that specimen throughput is often limited by the slowest direct sampling analyzer on the loop. One exception is the Bayer ADVIA system, which uses double tracks enabling specimens to bypass stations to get to their correct destinations. It should also be noted that if specimens are removed from their carriers on the line for testing, a system of queuing empty carriers is required to return the tubes to the conveyor.

In a second approach, instead of a continuous loop, some automated processing conveyor systems use a high-level sorting device to sort specimens into groups according to their routing destination in the laboratory, such as for hematology or chemistry tests. Downstream from the sorting device, separated specimens are routed down a dedicated conveyor line (Figure 11-17). This sorting method follows the approach used in most manual specimen processing areas; the extent of specimen transport via conveyor can depend on the activities to be included. For example, these designs may include a centrifuge and aliquoter, interfaced chemistry or immunochemistry analyzers, additional sorting, a take-out station, and even a refrigerated storage and retrieval station at the end of the chemistry line. The

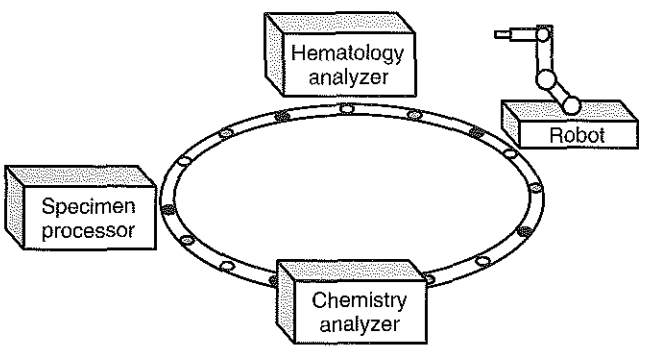

Figure 11-16 Direct sampling from a conveyor track in a loop configuration eliminates the need for separate equipment to sort specimens but may limit the rate of specimen movement on the track to the sampling speed of the slowest workstation. *(From Boyd JC, Felder RA, Savory J. Robotics and the changing face of the clinical laboratory. Clin Chem 1996; 42:1901-10.)*

hematology line may lead directly to hematology and coagulation analyzers and to an automated slide preparation machine.

In the third approach, sorting is integral to the conveyor system and specimens are sorted as they are transported (Figure 11-18). The advantages of this approach are that a dedicated specimen sorting device is not necessary in the specimen processing system, and that with appropriate specimen rerouting, the requirement for specimen aliquots may be avoided. Possible disadvantages of this approach are the expense of multiple bar code reading stations and specimen routing gates and the complexity of the process control software required.

Automated Sorting into Racks

Some systems are designed to sort the specimens into racks for transfer to particular laboratory sections or analyzers as described above. These systems (AI Scientific, Aloka, Olympus, Ortho-Clinical Diagnostics, and Tecan) sort the aliquot and original tubes into racks for manual transport to analyzers or lab sections. In some cases the racks may be specific for a specific analyzer, eliminating additional handling of tubes.

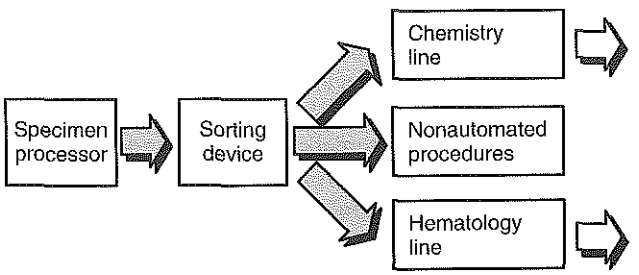

Figure 11-17 Sorting laboratory specimens before introduction to an automated specimen conveyor system simplifies the design and construction of the conveyor. *(From Boyd JC, Felder RA, Savory J. Robotics and the changing face of the clinical laboratory. Clin Chem 1996; 42:1901-10.)*

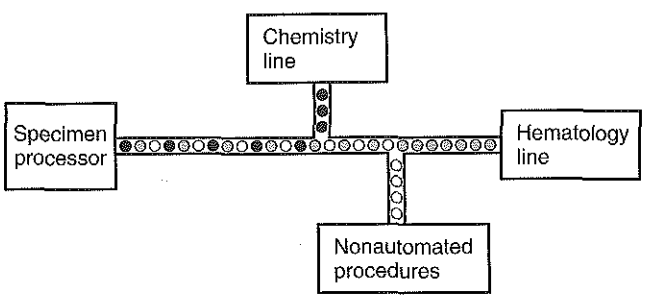

Figure 11-18 Use of the conveyor system to sort specimens dynamically during specimen transport eliminates the requirement for separate equipment to sort specimens, but requires a more sophisticated conveyor system with numerous bar code reading stations and gates to direct the specimens to the appropriate workstation. *(From Boyd JC, Felder RA, Savory J. Robotics and the changing face of the clinical laboratory. Clin Chem 1996; 42:1901-10.)*

Stand-Alone Sorting System

Some systems use a stand-alone sorting system, where specimens are manually loaded and unloaded (MDS AutoLab, Megamation, and Motoman). These systems require manual loading of tubes in racks or carrier devices; in some instances these may be analyzer specific racks or carriers. At speeds of 1000 tubes per hour or greater, tubes can be sorted into as many as 30 to 100 different sort groups. Typically the laboratory determines what each sort group is. The sort group could be all tests for a particular laboratory section, a group of closely related tests performed on the same analyzer or at the same bench, or an individual high-volume test. These systems may be very useful in a setting such as a reference laboratory, which may have many different tests and high volumes, but for which online centrifugation and aliquoting are less important considerations.

Automated Specimen Storage and Retrieval

Automated capability to store and retrieve specimens on demand is an important aspect of automated specimen delivery systems. A few of the integrated systems described above (e.g., Beckman Coulter) offer specimen storage and retrieval modules as options in their systems. These robotic modules store specimens refrigerated in specific locations that are logged into a database maintained by the specimen delivery system. When a user requests a specific specimen to be retrieved, the robot is given commands to retrieve the specimen from the appropriate archived location and to route the specimen to the requested station using the specimen transportation system.

A variety of free-standing refrigerated or frozen systems are also available and have been employed in some clinical laboratories. Biophile has a low temperature (−80 °C, etc.) robotic freezer, which is ideal for vials such as those used in molecular testing. Jouan Robotics has a robotic frozen storage system for microtiter plates. For laboratories with larger daily workloads, SK Daifuku, Diamond Phoenix, and Remstar each have different types of automated storage and retrieval systems that can be installed in either refrigerators or freezers. In these systems, trays or racks of specimens can be stored and retrieved by an operator or by using a robotic system, depending on the degree of automation desired.

PRACTICAL CONSIDERATIONS

In this section we discuss the practical considerations that influence a laboratory's decision to automate part or all of its operations. Included are discussions of evaluating a laboratory's requirements and other problems laboratorians face in integrating and automating their laboratories. The section concludes with a discussion on measuring the impact of automating a laboratory.

Evaluation of Requirements

Any consideration of total or modular laboratory automation should start with an evaluation of requirements.[42] Such

an evaluation begins with mapping of the current laboratory work flow from the arrival of patient specimens through completion of testing and reporting of results. Box 11-2 lists potential work-flow steps that should be mapped.

Middleton et al have described work-flow mapping in their discussion of process control and online optimization.[55] They relate the mapping of material (specimen) flows and data flows to process flow and show how such mapping assists the laboratory in determining process steps that are bottlenecks, steps that waste labor, and steps that are prone to errors. Work-flow mapping thus enables the laboratory to better identify what steps should be considered for automation. Although work-flow analysis at the beginning of an automation project may seem time consuming when the steps to be automated appear obvious, the authors believe that the mapping effort is well worth the investment in time and labor.

Some laboratorians use 80% as a "rule of thumb" in guiding decisions about automation. Clinical laboratories have many exceptional tests, specimen containers, and handling situations. Nevertheless, if 80% of the specimen containers and handling situations can be standardized and automated, the laboratory will achieve a dramatic reduction in its labor and costs, which should be sufficient to justify the investment in automation and the planning and evaluation time involved.

Once the laboratory's work flow has been mapped and its requirements have been identified, alternative solutions can be considered. Vendors are then invited to make presentations and to host visits of the laboratory management team to other laboratories where the vendors have successful installations. It is important at this stage to focus on the requirements identified by the work-flow mapping and not allow the vendor to try to sell equipment that may not be necessary.

Not every laboratory automation project has been successful. The authors believe that the poorer than expected results for at least some of those projects were due to inadequate planning and lack of evaluation of requirements. Box 11-3 lists 10 potential reasons why automation fails to meet expectations.

BOX 11-2 Clinical Laboratory Steps for Work-flow Mapping

Unpacking from transport containers
Presorting
Temperature preservation
Order entry
Document management (requisitions, etc.)
Labeling
Sorting
Centrifugation
Labeling of aliquot tubes
Pouring of aliquots
More sorting
Delivery to laboratory sections
More sorting
Preparing work lists
Decapping
Labeling analyzer-specific tubes for specimens
Pouring or pipetting analyzer-specific specimens
Loading tubes on analyzers
Performing tests (steps such as extraction, centrifugation, precipitation, dilution, etc., are not specifically listed)
Unloading analyzers
Recapping
Data manipulations (calculations)
Result review and verification
Reporting of results
Delivery of specimens to archival storage system
Archival storage of specimens
Reflexive testing
Repeat testing, diluting, if necessary
Additional physician-ordered testing
Specimen retrieval for additional or repeat testing
Disposal of expired specimens

Problems of Integration

Building a highly integrated laboratory generates many potential problems. Because it is unlikely that a laboratory will use only the equipment of a single equipment manufacturer, integration of the instruments and robotic devices from different manufacturers is necessary. Decisions must be made concerning which device will be the master controller and which company will develop the software that provides overall control of the automation scheme. In addition, individuals or firms who will be responsible for configuration of the automation to the geometry and production schedule of the laboratory must be recruited and trained. Although industrial automation schemes have been developed to solve

BOX 11-3 Ten Reasons Why Automation Fails to Meet Expectations

- Incomplete understanding of current environment, processes, costs, customer expectations
- Loss in flexibility because of fixed processes and limited throughput
- Unrealistic expectations of system—cost reduction, throughput, return on investment
- Unplanned and poorly developed "workarounds" required to interface automation with manual processes
- Unclear expectations of system functionality
- Overbuilt and unnecessarily complicated system design
- Inadequate technical support
- Credible and realistic impact analysis never conducted
- Hidden costs—labor, supplies, maintenance
- Failure to optimize current processes before automation (never automate a poor process)

Modified from Argent Global Services, Solutions Newsletter, page 4, April 2003, Oklahoma City, Okla.

many of these problems, there is as yet insufficient experience with these approaches in the very different operating environment of a clinical laboratory.

The reader is referred to the NCCLS standard AUTO3-A, which is described in the following and in particular to the Functional Control Model (Section 4.2), which describes the relationships between the LIS, LAS, and various devices. In this model, and throughout the series of NCCLS automation standards, the term LAS represents the computer system that controls the automation system, not the actual automation hardware. Most often, it is the LAS that has the requisite process control software to support automation. The functional control model, which is depicted in Figure 11-19, supports analytical instruments that may be physically attached to the automation system and analyzers that may not be attached but are still interfaced to the LIS. The model does not give dominance to either the LIS or the LAS, but rather allows for essential information flows in either direction to make the most efficient use of the strengths of each system.

Although laboratory automation has the potential to improve laboratory productivity and reduce operational costs,[76] integrated laboratory automation has not always proven to be cost effective. Tatsumi et al[84] have reviewed the Japanese experience with integrated laboratory systems and found that these systems do not always succeed in reducing laboratory costs. With an increasing emphasis on cost-effective laboratory testing in Japan, many hospitals there have replaced total laboratory systems with smaller modular systems that allow rapid and convenient testing and are responsive to the political changes in the Japanese healthcare system.

Device Integration

One objective in developing an integrated laboratory is to link laboratory instruments and devices into an automated system to maximize the number of functions automated.

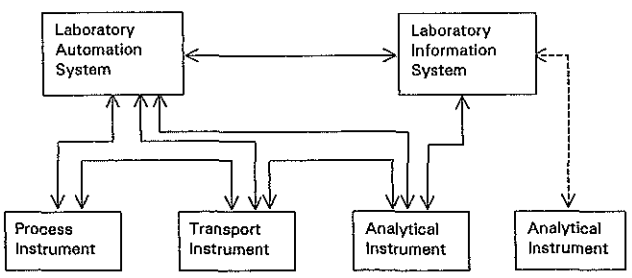

Figure 11-19 Functional control model of NCCLS AUTO3-A standard. The solid lines and arrows depict logical information flows supported by the standard. The dotted line and arrows are logical information flows permitted, but not supported, by the standard. *(National Committee for Clinical Laboratory Standards [NCCLS]. Laboratory automation: Communications with automated clinical laboratory systems, instruments, devices, and information systems, approved standard. NCCLS Document AUTO3-A Wayne PA: NCCLS, 2000. Figure reproduced with permission of NCCLS.)*

Automatic specimen introduction requires the development of mechanical interfaces between each laboratory analyzer and devices such as conveyor belts, mobile robots, or robot arms. Enhancements to electronic interfaces for laboratory instruments are necessary to allow remote computer control of front-panel functions, notification of instrument status information, and coordination of the distribution of specimens between instruments. Most existing LIS interfaces with laboratory analyzers provide only the ability to download accession numbers and the tests requested on each specimen, and to upload the results generated by the analyzer.

Process Controllers and Software

Process controllers provide computer integration of the many decision-making tasks that occur in the daily activity of a laboratory. Consequently, process control software is needed to coordinate the overall activities of the laboratory. To integrate the various devices in the laboratory, communications with a master controller device must be established. In addition, communication is needed between the LIS computer, the LAS computer (that provides process control), the laboratory analyzers, and the specimen conveyor and specimen manipulation devices, such as automated centrifuges, aliquoters, decappers, etc. The distribution of tasks must be carefully specified in developing such a communications network. A possible distribution of tasks is the following:[12]

1. The LAS assumes responsibility for assigning a dispatch priority and schedule to each specimen, providing specimen tracking information to the LIS, rerouting specimens for reanalysis, implementing reflex orders, and troubleshooting, and has final authority in resolving any priority conflicts that arise in specimen handling.
2. The LAS also controls specimen distribution. It monitors all specimen distribution system bar code readers and gates, routes specimens to workstations as required, monitors specimen tracking information, monitors instrument status, alerts an operator of any instrument problems, and notifies instruments of each specimen that has to be sampled.
3. The LIS downloads specimen information to instruments and the LAS, monitors and provides to users all information related to specimen tracking received from the LAS, and receives all completed laboratory test results from each analyzer. Software with user-definable algorithms for automatic reflex testing may reside in either the LAS or the LIS depending on system capabilities and the overall design.

This list of tasks is not necessarily complete but demonstrates the complexity of the software engineering task of integrating automation in a laboratory. Although the functions of the LIS and LAS are often provided on separate computers, they may also be integrated on a single computer. Several manufacturers (e.g., MDS AutoLab, Odysis, and Zymark) have process control software that can manage many functions in an automated laboratory. However, the

integration of the LAS functions with the LIS functions remains a formidable project often requiring the development of custom software.

Measuring the Impact of Automation

It is highly recommended that performance metrics be used to assess the performance of automation systems to objectively determine whether the implementation has been successful in meeting the original objectives and to monitor continued improvement. This statement is applicable, whether the automation is a simple mobile delivery robot or a total laboratory automation system with specimen processing and integrated analyzers. Ideally, the metrics should be identified and implemented in advance of implementation of the automation to establish an adequate baseline for comparison. Recommended parameters for measurement include stat and routine turnaround time at median and 90 or 95 percentiles; quality parameters, such as lost specimens, mishandled specimens, mislabeled specimens, misdelivered specimens, and aliquoting or pouring errors; and productivity parameters, such as requisitions or orders processed per employee, billed units reported per employee, etc. Since automation usually improves employee safety, postautomation employee accidents may decrease. Automation also may improve employee job satisfaction and reduce training time, so measures such as employee turnover rates are useful.

DEVELOPMENT OF STANDARDS FOR LABORATORY AUTOMATION

The rate of development of standards continues to influence the speed of technical advancement in the field of laboratory automation. Typical laboratory instruments are interfaced to LIS systems using either the RS 232C serial or 802.3 Ethernet connection standards. The latter may often be set up using Transmission Control Protocol/Internet Protocol (TCP/IP), through local area network (LAN) connections, and may also use an interface engine. The American Society for Testing and Materials (ASTM) standards E1391 and E1384 are the more commonly used communication standards, although the newer NCCLS standard AUTO3-A (see next paragraph) now offers many improvements over ASTM. The commonly used cabling standards employed are IEEE-422 serial or IEEE-488 parallel. Although these electronic standards help to reduce the work involved in development of an interface, each interface with a laboratory device must still be developed individually and tested.

The NCCLS has developed standards to meet the requirements of vendors and users of clinical laboratory automation systems. Five standards have now been published at the approved level dealing with specimen container and specimen carrier[59]; bar codes for specimen container identification[60]; communications with automated clinical laboratory systems, instruments, devices, and information systems[61]; systems operational requirements, characteristics, and information elements[62]; and electromechanical interfaces.[63] The communications standard was developed in collaboration with Health Level Seven (HL7). A new chapter of the HL7 standard (Chapter 13), which appears in HL7 version 2.4[46] and newer versions, was written specifically to address the requirements for laboratory automation communications, which had not been met by the older standards developed by ASTM.[2,3] The NCCLS communications standard[61] includes all of HL7 Chapter 13 plus additional information of value in applying the HL7 communications standard to specific automation requirements. In addition to the new Chapter 13, some changes were also made in Chapters 4 and 7 of the HL7 standard to coordinate with the automation requirements detailed in Chapter 13. Vendors and users of automation are therefore advised to obtain both the HL7 and NCCLS standards.

The NCCLS has an Area Committee on Automation and Informatics, which oversees the above standards and initiates new standards development projects. Current standards development projects include Data Content for Specimen Identification, Protocols to Validate Laboratory Information Systems, and Remote Access to Hospital Diagnostic Devices via the internet. In 2002, ASTM transferred to NCCLS the ownership and copyright of all nine standards in its E31.13 group, including the two standards referenced above. These standards all relate to the clinical laboratory, with some of them simply preceding or overlapping the NCCLS automation standards. NCCLS is now in the process of evaluating which of these standards will be maintained and updated and which may be abandoned.

OTHER AREAS OF AUTOMATION

In addition to the automated devices and processing units that were developed primarily to automate chemistry and immunoassay that are described above, a variety of other instruments and processes have been automated and used in the clinical laboratory. They include urine analyzers, flow cytometers, hematology cell counters, nucleic acid analyzers, microtiter plate systems, point-of-care analyzers, and remotely located systems.

Urine Analyzers

Many of the same analytical principles are used for the quantitation of serum and urine constituents, but it is more difficult to automate testing of urine than serum, because the broad range of concentrations of many urine constituents requires a low limit of detection to measure low concentrations, and expanded linearity to permit measurements of high concentrations without dilution. This requirement, together with the relatively low demand for urine tests compared with that for serum tests, has restricted the development of analyzers designed specifically for urine constituents. Nevertheless, selected urine analyses are performed on the available analyzers in some institutions.[40]

Flow Cytometers

Cytometry refers to the measurement of physical and/or chemical characteristics of cells, or, by extension, of other biological particles. Flow cytometry is a process in which such measurements are made while the cells or particles pass, preferably in single file, through the measuring apparatus in a fluid stream (see Chapter 3). Flow sorting extends flow cytometry by using electrical or mechanical means to divert and collect cells with one or more measured characteristics falling within a range or ranges of values set by the user.

Flow cytometers are used in the clinical laboratory to analyze cells that have been stained with a supravital or fluorescent dye (although unstained cells can also be measured) and travel in suspension one by one past a laser light source. Scattered and emitted light is collected in front of the light source and at right angles, respectively (see Chapter 3). Information derived by measuring *light scatter* when a cell is struck by the laser beam can be used to estimate cell shape, size, cellular granularity, nuclear lobularity, and cell surface structure. Some cell counters classify white cells using the Coulter principle, cell conductivity, and light scattering of unstained cells (e.g., Gen-S, HmX, and MAXM) to differentiate cell types, whereas other cell counters (ADVIA-120) use two flow cytometry channels (one with peroxidase-stained, fixed cells, one with unstained or lysed cells). The Cell-Dyn 4000 uses one flow cytometry channel and aperture resistance to count white blood cells and light scattering from unstained cells measured at four different light-scatter angles to provide a five-part differential analysis. The aperture resistance transducer is also used to provide the red blood cell and platelet counts. The Sysmex XE-2100 uses flow cytometry with light scattering measured at three angles to determine the white cell count and differential. A separate channel provides additional information on the presence of immature white blood cells. This channel uses a hemolytic reagent that selectively protects immature white blood cells that are counted using the Sysmex radiofrequency direct current detection method.

Hematology Cell Counters

Analyzers that perform a complete blood count have been automated using the Coulter principle, cell conductivity, light scatter, and flow cytometry. Individual blood cells are analyzed by application of one or more of these techniques. The *Coulter principle* is based on changes in electrical impedance, which are produced by nonconductive particles suspended in an electrolyte as they pass through a small aperture between electrodes. In the sensing zone of the aperture, the volume of electrolyte displaced by the particle (cell) is measured as a change in voltage that is proportional to the volume of the particle. By carefully controlling the quantity of electrolyte drawn through the aperture, several thousand particles per second are individually counted and sized. An electronic correction is applied if more than one cell passes through the aperture at the same time. Red blood cells, white blood cells, and platelets can be identified by their size. Alternating current in the radiofrequency range short circuits the bipolar lipid layer of the cell membrane, allowing energy to penetrate the cell. Information about intracellular structure, including chemical composition and nuclear volume, can be collected using this technique, known as *cell conductivity.*

Nucleic Acid Analyzers

Automation of the analysis of nucleic acids developed rapidly as an outgrowth of the Human Genome Project.[49] Several manufacturers have developed automation to assist with the isolation of nucleic acids and with analysis of nucleic acids using several amplification schemes. Two common examples of such analyzers are presented below.

The MagNA Pure LC Instrument allows automated isolation and preparation of nucleic acids. The instrument performs up to 32 nucleic acid isolations in 1 to 3 hours from various specimens, which can include blood, blood cells, culture cells, plasma, serum, sputum, stool, broncho-alveolar lavage, plant tissues, or food products.

Specimen identifications are entered at the user terminal or acquired by reading bar codes. All subsequent steps are performed automatically. Nuclease-free disposable reaction tips are used for transfer of specimens and as reaction vials. Separation of nucleic acids is carried out using magnetic beads, washing steps, and elution of nucleic acids from the beads into the cooled specimen cartridge. Used reaction tips are automatically discarded into an attached autoclavable waste bag and liquid waste is pipetted at the end of the run into an appropriate waste container. The device provides increased reproducibility and scalability of purification and reduced risk of cross contamination when compared with standard manual methods. Following nucleic acid purification, the MagNA Pure can transfer the nucleic acid to various container types (programmable by the user) including capillaries, 96-well polymerase chain reaction (PCR) plates, A-rings, or tubes. The instrument can provide pager notification to the user regarding the status of the instrument and the processes.

The LightCycler system combines a thermal cycler platform with a fluorescence detection system. The unique design of this device allows real-time monitoring of amplification cycles and melting temperature curves. Each amplification specimen is placed in a glass capillary with a maximum capacity of 20 μL. The capillary is tightly closed to prevent contamination and is not opened at any time during analysis. The small specimen volume saves reagents, and the high surface-to-volume ratio of the capillary allows very fast heating and cooling. Fluorescence emitted during the PCR process is focused on the tip of the capillary. The instrument uses air for heating and cooling. Given the very low thermal capacity of air and the high surface-to-volume ratio of the capillary, the temperature can be changed very rapidly (about 20 °C per second). Thus thermal cycling can occur at very rapid rates. A typical amplification cycle

requires only 30 to 60 seconds, which means that an amplification reaction with 30 cycles is usually completed within 15 to 30 minutes. The amplification products are quantified by fluorescence measurement using a single microvolume fluorimeter. The fluorimeter uses a blue LED that emits light at 470 nm as an excitation source and provides three channels that detect emitted light with wavelengths of 530 nm, 640 nm, and 710 nm.

The LightCycler instrument can use fluorescence-labeled, sequence-specific hybridization probes (oligonucleotides) for the specific detection of amplification products. This detection format permits high-throughput genotyping without the requirement for any post-PCR specimen manipulation. Once suitable oligonucleotides are designed, the genotyping of a specimen is straightforward. The instrument is programmed to amplify the DNA and to perform a subsequent melting curve analysis.

Microtiter Plate Systems

Microtiter plate systems are commonly used in immunoassays and nucleic acid analyses. As used for enzyme-linked immunosorbent assay (ELISA) assays, microtiter plates usually are made of polystyrene and have 48 or 96 wells coated with antibody specific for the antigen of interest. After incubation of serum in the microtiter plate well, the well is washed to remove unbound antigen, and a second antibody with conjugated indicator enzyme is added. After a second incubation period, the well is washed to remove the unbound conjugate. Color is developed by the addition of enzyme substrate and the reaction is terminated at a set time. With the development of automated pipetting stations (e.g., Gilson Model 215, Hamilton Microlab FAME, and Perkin Elmer Multiprobe), the liquid handling steps required for microtiter plate assays have been fully automated to make microtiter plate assays a viable technology for carrying out large numbers of immunoassays. Automated pipetting stations have a cartesian robot with a pipette fixed to the end of a probe that moves about a rectangular space. The probe is capable of moving in the X, Y, and Z axes. Liquids may be aspirated and dispensed in any location within the rectangular space.

Automated Pipetting Stations

Pipetting stations may be used to automate an analytical procedure for which an automated analyzer does not exist or cannot be cost justified. Most pipetting robots are relatively easy to program, rarely malfunction, and can deliver liquids with extreme precision and accuracy. Multiple-channel pipetting robots allow parallel processing of specimens with 8- or 12-channel probes to handle microtiter plates.

POCT Analyzers

Point-of-care testing (POCT) is a rapidly growing component of laboratory testing. It is known by a variety of names, including "near-patient," "decentralized," and "off-site" testing and is discussed in detail in Chapter 12. In addition, technologies incorporated into POCT analyzers are discussed in Chapters 4 and 10 and examples of POCT glucose analyzers are described and discussed in Chapter 25.

Remote Automated Laboratory System

Unmanned satellite laboratories are a possible alternative to a central laboratory facility. To demonstrate the practicality of such an approach, investigators at the University of Virginia have developed remote automated laboratory systems (RALS) designed to automate POCT in hospital intensive care units. The results from the analytical instruments in each RALS are sent to a central monitoring workstation several floors away from the satellite laboratory by a network interface, where results are viewed and either accepted or rejected by a trained medical technologist before being released for clinical use. Error codes built into the analytical instruments are also passed to the main laboratory by the computer network. Technologists in the control center can also shut down the satellite laboratory when necessary, as in the case of instrument failure. Patient information is downloaded from the hospital information system in real time so that users can select their patients and the tests to perform from a list presented on the computer touchscreen.

CHAPTER 12

Point-of-Care Testing

Christopher P. Price, Ph.D.,
and Andrew St. John, Ph.D., M.A.A.C.B.

Point-of-care testing (POCT) is a rapidly growing component of healthcare services* and is used in many healthcare settings (Box 12-1). They include coronary care units,† intensive care units,[45,96,153] surgical wards,[12,19,34] emergency wards,[40,146] pediatric units,[41,128] and for monitoring both acute[46,52,91] and chronically ill patients.‡ For the purpose of this chapter, POCT is defined as "any test that is performed at the time at which the test result enables a decision to be made and an action taken that leads to an improved health outcome." Other terms used to describe POCT include "bed side,"[107] "near patient,"[28] "physician's office,"[88] "extralaboratory,"[114] "decentralised,"[5] "off site," "ancillary," and "alternative site"[49,106] testing. Reduced turnaround time (TAT) of test results[119] and improved patient management are advantages of this type of testing (Box 12-2).[75]

In the early days of diagnostic testing, tests were undertaken close to the patient—at the point-of-care—integrating information gained from simple tests into the clinician's observation of the patient's current symptoms and previous history (Figure 12-1).[117] With technical progress in the development and availability of sophisticated analyzers and analytical systems, these tests moved away from the patient and were analyzed in a central or core clinical laboratory where all samples were transported for subsequent analysis. Eventually, this resulted in a disconnect in the time between the individual, specimen(s), physician, laboratory, results, and medical decision making process (Figure 12-2). This has led to logistical, management, and analytical problems in laboratory operations and an increase in the TAT of test results from minutes to hours and sometimes even days. With the trend toward miniaturization of components (see Chapters 4 and 10) and their integration into small, self-contained, analytical systems, the means became available of returning to POCT with a goal of reducing TAT of test results and improving patient management (Box 12-2).

The following sections of this chapter will describe the technology available for POCT and the organizational factors that are important when POCT is implemented in a healthcare setting. The chapter concludes with a short discussion of the future of POCT.

ANALYTICAL AND TECHNOLOGICAL CONSIDERATIONS

The technical advances that have catalyzed the evolution of POCT instruments are the development of a miniature sensor to measure electrolytes, blood gases, and other analytes and the development of dry, stable reagents in disposable unit-dose devices. Although the throughput of tests for these systems is low, the time required to produce the results is usually short. These systems are often small enough to be portable, further enhancing the possibility of "bringing tests to the patient."

Topics to be discussed in this section include (1) instrument requirements, (2) instrument and operator interface design, (3) examples of POCT devices, and (4) the role of informatics. Readers requiring additional information are referred to more comprehensive texts[74,115] or to the vendors of POCT devices.

Requirements

All POCT devices should meet the following overall requirements: (1) simple to use, (2) robust in terms of storage and usage, (3) producing results concordant with the central laboratory and consistent with the clinical need,and (4) capable of being safely operated. Additional characteristics and requirements of POCT devices are listed in Box 12-3.

BOX 12-1 Environments Where Point-of-Care Testing Might Be Employed

Primary Care
Home
Community pharmacist
Health centers (general practice, primary care)
Workplace clinic
Physician's office and community clinic
Diagnostic and treatment center
Paramedical support vehicle (ambulance, helicopter, aircraft)

Secondary and Tertiary Care
Emergency room
Admissions unit
Ambulatory diagnostic and treatment center
Operating room
Intensive care unit
Ward
Outpatient clinic

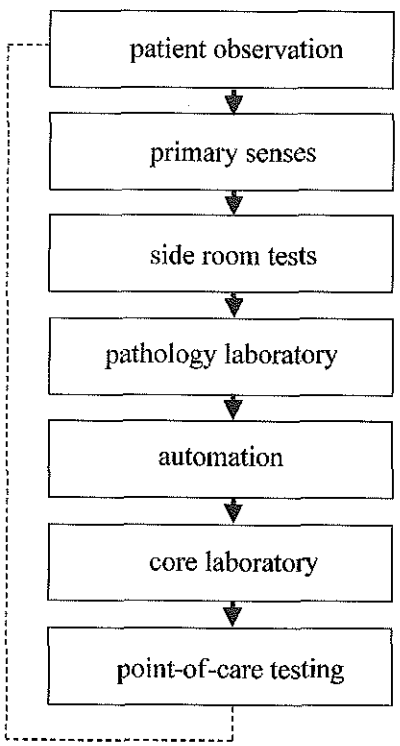

Figure 12-1 The trend in the evolution of diagnostic testing from observation of the patient, through simple testing, to sophisticated testing in the laboratory and back to a more patient-centered approach.

BOX 12-2 Advantages of Point-of-Care Testing

Reduced TAT of test results
Improved patient management
Reduction in the administrative work associated with test requesting
Minimization of delays occurring during sample collection and sample requirement(s)
Reduction in the time delay resulting from the transport of the sample to the testing lab
Reduction in the time delay resulting from having to log in (register) the sample
Reduction in the time delay that results from the entry of a sample into a complex testing facility

BOX 12-3 Characteristics/Requirements of a Point-of-Care Testing Analyzer

First results in a minute or less
Portable instruments with consumable reagent cartridges
A one- or two-step operating protocol
The capability of performing direct specimen analysis on whole blood and urine (nonprocessed samples)
Simple operating procedures that do not require a laboratory-trained operator
Flexible test menus
Quantitative results with accuracy and precision comparable with those of the central laboratory
Built-in/integrated calibration and quality control
Ambient temperature storage for reagents
Results provided as hard copy, stored, and available for transmission
Low instrument cost
Service by exchange
Built-in regulatory record keeping

Modified from Maclin E, Mahoney WC. Point-of-care testing technology. J Clin Ligand Assay 1995;18:21-33.

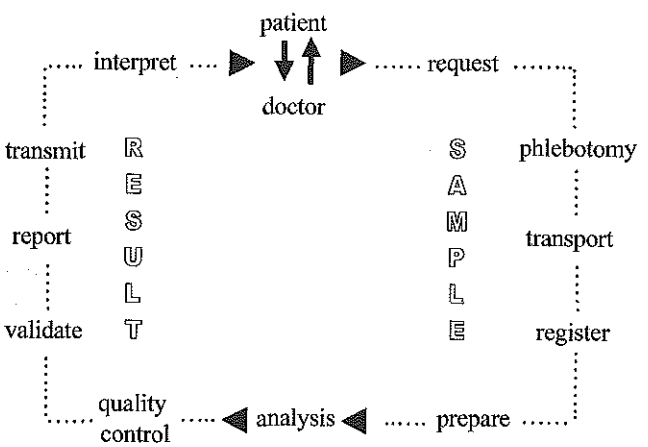

Figure 12-2 A schematic representation of the key steps in requesting, delivering, and using a diagnostic test result.

Design

There is a great diversity of devices being used at point-of-care, ranging from relatively simple dipstick or strip tests to large, bench top, chemistry analyzers (Table 12-1). This breadth of technology encompasses a large range of analytes (Table 12-2), and many of the devices use the same analytical principles, such as enzymatic conversion and antibody recognition, as those found in conventional mainframe laboratory analyzers. The design of individual components or processes to be considered for POCT devices includes (1) operator interface, (2) bar code identification systems, (3) sample delivery devices, (4) reaction cell, (5) sensors, (6) control and communications systems, (7) data management and storage, and (8) manufacturing requirements.

Operator Interface

The operator or user interface is a very important design feature of POCT devices and should require minimal oper-

TABLE 12-1 Classification of Types of Point-of-Care Testing Instruments or Devices

Type of Technology	Analytical Principle	Analytes
Single-use, qualitative or semiquantitative cartridge/strip tests	Reflectance	Urine and blood chemistry
	Lateral-flow or flow-through immunoassays	Infectious disease agents, cardiac markers, hCG
Single-use quantitative cartridge/strip tests with a reader device	Reflectance	Glucose
	Electrochemistry	Glucose
	Reflectance	Blood chemistry
	Light scattering/optical motion	Coagulation
	Lateral-flow, flow-through, or solid phase immunoassays	Cardiac markers, drugs, CRP, allergy, and fertility tests
	Immunoturbidimetry	HbA_{1c}, urine albumin
	Spectrophotometry	Blood chemistry
	Electrochemistry	pH, blood gases, electrolytes, metabolites
Multiple-use quantitative cartridge/bench top devices	Electrochemistry	pH, blood gases, electrolytes, metabolites
	Fluorescence	pH, blood gases, electrolytes, metabolites
	Multiwavelength spectrophotometry	Hemoglobin species, bilirubin
	Time-resolved fluorescence	Cardiac markers, drugs, CRP
	Electrical impedance	Complete blood count

TABLE 12-2 Examples of Single or Multipad Stick Tests

Test	Sample	Chemistry
Acetaminophen	Whole blood	Acyl dehydrogenase
Alanine aminotransferase	Whole blood	Alanine/glutamate
Albumin	Whole blood, urine	Dye binding
Cholesterol	Whole blood	Cholesterol oxidase
Creatinine	Whole Blood, urine	Copper complexation
Glucose	Whole blood	Glucose oxidase
Lactate	Whole blood	Lactate dehydrogenase
Uric acid	Whole blood	Uricase
Alcohol	Urine	Alcohol dehydrogenase
Bilirubin	Urine	2,4-dichloroaniline
Hemoglobin	Urine	Peroxidase activity
Leukocyte esterase	Urine	Pyrrole amino ester hydrolysis
Ketones	Urine	Sodium nitroprusside reaction
Nitrite	Urine	p-Arsanilic acid reaction
pH	Urine	Double indicator principle
Protein	Urine	Protein error of indicators
Specific gravity	Urine	Polyacid pH change
Urobilinogen	Urine	Ehrlich's reaction

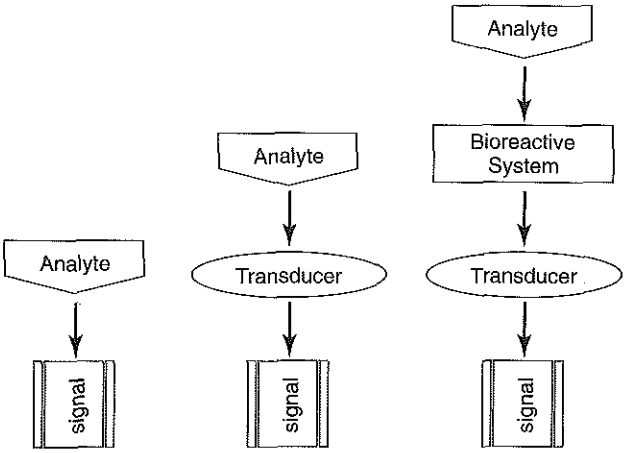

Figure 12-4 Diagram showing the key types of sensor technology used in POCT instruments.

ator interaction, guide the user through the operation, and tolerate minor operator errors. A minimum number of steps should include identifying the operator, patient, and test to be measured. Advances in information technology and consumer electronics have had a major impact on this area, such as the production of inexpensive liquid crystal display (LCD) screens.[89] Other forms of user interface include keypads, bar code readers, and possibly a printer. In some devices, the display is the only means to show the result, and in others it may incorporate a touch screen that is used to control the device (Figure 12-3). An alternative to the touch screen is a membrane type of keypad, but both displays and keypads can lead to significant increases in the size of the device when other user demands require smaller devices.

Bar Code Identification Systems

Many POCT devices incorporate bar code reading systems for a number of purposes. These include (1) identifying the test package to the system, (2) incorporating factory calibration data, and in some cases (3) programming the instrument to process a particular test or group of tests. Some POCT devices use magnetic strips as a way of storing similar information, such as lot-specific calibration data. Other functions of a bar code reader that are of growing importance are to identify both the operator and the patient sample to the system. This will ensure that there is traceability of the person who performed the test, and that the results are linked to the correct patient.

Sample Delivery

Sample access and delivery of the sample to the actual sensing component of the strip, cassette, or cartridge are also key interactions of the user with the device and in some cases, removal of the sample may also require user intervention. Ideally, following the addition of the sample, results should be produced without further intervention.

Reaction Cell

The design of the location where the analytical reaction takes place can be very simple, such as a porous pad, a cell, or a surface within a chamber. However, to simplify the user interface, it is often necessary to design complexity into the reaction chamber. Advances in microfluidics and techniques, such as molding, micromachining, photolithography, and screen printing, have all played a substantial role in the development of POCT devices.[71,78]

Sensors

Much of the focus on POCT devices has been concerned with the advances in sensor design (see Chapter 4).[140] Various sensor designs are illustrated in Figure 12-4. The chemosensor shown in the first column of Figure 12-4 is an example where the analyte has an intrinsic property, such as fluorescence, that enables it to be detected without a recognition element. The chemosensor shown in the second column of Figure 12-4 is a much more common design and is used in many POCT devices. The transducing element might be a chemical indicator or binding molecule that recognizes the analyte to be measured and produces a signal, usually electrical or optical. A biosensor is shown in the third column of Figure 12-4 and is distinguished from a chemosensor by having a biological or biochemical component as the recognition element. Enzymes are the most common biological element used followed by antibodies; transduction can be via an optical or electrical signal.

Control and Communications Systems

These constitute a major component of all POCT devices other than qualitative or semiquantitative strip tests that do not require a reader or measurement device. In even the smallest device, there is a control subsystem that coordinates all the other systems and ensures that all the required processes for an analysis take place in the correct order. Operations that require control include insertion or removal of the strip, cartridge, or cassette; temperature control; sample injection or aspiration; sample detection; mixing; timing of the detection process, such as absorbance measurement; and waste removal. Fluid movement can often be

accomplished by mechanical means through pumps or centrifugation, and by fluidic properties, such as surface tension; the latter is often a critical element in the design of the simple strip tests and in microfabricated systems.[71]

Data Management and Storage

There are substantial requirements for data storage for POCT devices and in some cases data management, depending on the size and complexity of the device and testing menu. Data management includes calibration curve data and quality control (QC) limits and patient results. In some systems, data transfer and management takes place when the meter or reader is linked to a small bench top device called a docking station. These and other devices include communication protocols that allow data to be transferred to other data management systems.

Manufacturing of POCT Devices

Since many POCT methods are only used once and then discarded, reproducibility of manufacture is a key requirement so that consistent performance extends across a large number of strips or devices. The manufacturing process includes steps that are taken to ensure that the devices are reproducible (e.g., with respect to fluid movement) and remain stable during transit and storage for the stated period of time (e.g., with respect to calibration and reagent performance.)

Examples of POCT Devices

POCT devices are classified as (1) in vitro and (2) in vivo, ex vivo, or minimally invasive.

In Vitro Devices

A 2003 survey of POCT analyzers, excluding glucose meters, indicated that the majority of POCT analyzers were in vitro devices and performed their analysis on whole blood, although others used serum, plasma, urine, or saliva samples.[36] The majority of instruments used less than 100 µL of the sample, and there were more than 15 different detection systems used for analytical measurement. The diversity of in vitro POCT technology and the range of analytes make it difficult to devise a simple classification that avoids any overlap between various technologies. For the purposes of highlighting key or novel POCT technologies, the following discussion classifies the various devices largely according to size and complexity: (1) single-use cartridge and/or strip tests, (2) single-use quantitative cartridge and/or strip tests with a monitoring device, and (3) multiple-use cartridge and bench top systems.

Single-Use Qualitative Strip or Cartridge and/or Strip Devices

A wide range of devices fall into this category, including single-pad urine tests (dipsticks) that are read visually; more complex strips that use light reflectance for measurement; and fabricated cassettes or cartridges that incorporate techniques such as immunochromatography[116] and are used as immunosensors.

Dipsticks. Dipsticks are single-pad devices that are relatively simple in construction and are composed of a pad of porous material, such as cellulose, that is impregnated with reagent and then dried.[154]

Complex Strips. More complex pads are composed of several layers, the uppermost of which is a semipermeable membrane that prevents red cells from entering the matrix. Despite their simplicity, critical operator factors include the need to cover the whole pad with the sample. Because the reactions often do not proceed to completion, it is necessary to time the period between placing the sample on the pad and comparing the resulting color to a color chart. In addition, for blood tests it may be necessary to remove all the blood before placing the sample in the reflectance meter; sometimes it is possible to read the color from the underside of the strip. Developments of these single stick devices include two pads for measurement of (1) different concentrations of the same analyte, such as hemoglobin and glucose[150]; (2) both albumin and creatinine (semiquantitative) to provide an albumin-creatinine ratio[120]; and (3) up to 10 different urine analytes using reflectance technology.[82] A chromatographic device has also been developed for the quantitative measurement of cholesterol, which does not require the use of any instrumentation.[1] Table 12-2 lists the tests performed by single or multipad dipsticks and the chemistry used for analysis.

Immunosensors. These devices are biological sensors in which the recognition agent is an antibody that binds to the analyte (see Chapters 4 and 9). Detection of the binding event or signal transducer is usually via an optical mechanism, either reflectance or fluorescence spectrophotometry, for quantification. Most immunosensing devices use reactions that are not reversible, although reversible reactions have now been described, which will facilitate their application in multiple-use cartridges and similar formats in the future.[57] Immunosensors usually use solid phase technologies in conjunction with either flow-through, lateral-flow, or immunochromatography processes. In the flow-through format, a heterogeneous immunoassay takes place in a porous matrix cell that acts as the solid phase, and in lateral flow the separation stage take place as the sample passes along the porous matrix.

A typical immunoassay format in a flow-through device has an antibody covalently coupled to the surface of a porous matrix. When the patient sample is added to the matrix, the analyte of interest binds to the antibody. Addition of a second labeled antibody forms a sandwich and traps the label at the position of the first antibody.[144] If the label is gold sol particles or colored latex, the label is directly visualized or quantified by reflectance spectrophotometry in a separate reader.[3] Another important feature of this type of technology is the incorporation of a built-in quality monitor that indicates positive if all the reagents have been stored and the device operated correctly. In all these different formats,

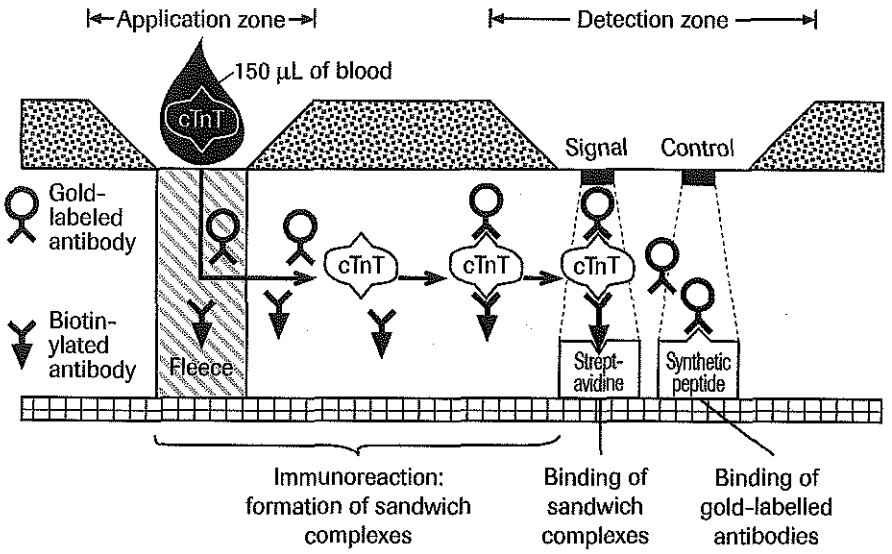

Figure 12-5 Schematic diagram of a lateral flow immunoassay for troponin T. *(Courtesy Roche Diagnostics, Mannheim, Germany.)*

uniform and predictable flow of the sample through or along the solid phase matrix is a major determinant of the reproducibility of the technique. Therefore the choice of matrix and how it interacts with the sample is of particular importance, and advances in the understanding of solid phase and surface chemistry technology have made a major contribution to the development of immunosensors.[131]

The Roche Trop T test strip for the qualitative determination of troponin T is an example of this technology (Figure 12-5). In this device, the blood sample is added and first flows through a glass fiber fleece, that separates the plasma from whole blood. Simultaneously, two monoclonal antihuman cTnT antibodies, one conjugated to biotin and one labeled with gold particles, bind to the troponin T in the sample. The antibody troponin complex then flows in a lateral direction along the cellulose nitrate test strip until it reaches the capture zone, which contains streptavidin bound to a solid phase. The biotin in the antibody troponin complex binds to the streptavidin and immobilizes the complex. The complex is then visualized as a purple band by the gold particles attached to one of the antibodies.[3] The unreacted gold-labeled antibody moves farther down the strip where it is captured by a zone containing a synthetic peptide consisting of the epitope of human cardiac troponin T and is visualized as a separate but similar colored band. The presence of this second band serves as an important quality indicator, because it indicates that the sample has flowed along the test strip, and the device has worked correctly.

A growing application of the strip type of technology for immunoassay is for infectious disease testing and the rapid detection of various infectious antigens and antibodies including *Chlamydia*,[21,62] group A streptococci,[20] *Helicobacter pylori*,[50] infectious mononucleosis,[39] and human immunodeficiency virus.[64,67] These tests commonly use a lateral-flow format for urine, serum, plasma, or whole blood samples in conjunction with analytical techniques, such as enzyme immunoassay and immunochromatography. An alternative

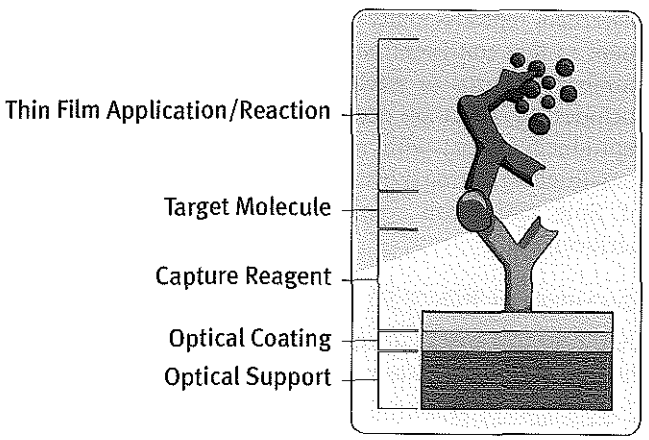

Figure 12-6 Schematic diagram of the principles of an optical immunoassay (OIA®) using thin film detection. *(Courtesy Thermo Electron Corporation, Louisville, CO.)*

approach manufactured by the Point-of-Care and Rapid Diagnostics business unit of the Thermo Electron uses light reflection and thin film amplification in what are termed optical immunoassays. The presence of an infectious disease antigen, such as Streptococcus A, is detected through binding to an antibody coated on a test surface. Light reflected through the antibody film alone produces a gold background that changes to purple when the thickness of the film is increased because of the presence of an antigen (Figure 12-6). The tests include built-in controls and provide results comparable with those provided by conventional microbiological assays but much more rapidly.[44]

Although most single-use devices currently rely upon reflectance or absorbance as the detection mechanism, other techniques of measurement are being investigated including surface plasmon resonance, evanescent wave, fixed-polarized ellipsometry, and diffraction. For example, evanescent wave technology has been used for the measurement of cardiac markers.[94,138]

Single-Use Quantitative Cartridge and Strip Tests with a Monitoring Device

The technologies or devices described in this section differ from those described above in that they include a meter or monitoring device, thereby enabling detection and quantification of the analyte(s). The availability of small, compact detectors is a result of advances in modern electronics and miniaturization. An integral part of many of these instruments is a charge-coupled device (CCD) camera that is a multichannel light detector, similar to a photo multiplier tube in a spectrophotometer, but with a higher signal to noise ratio so that it can detect much lower signals at low levels of light. For example, the Roche Cardiac Reader contains a CCD that can quantitate separate lateral-flow immunoassay strips for measurement of troponin T,[3,26] myoglobin, and D-Dimer. The majority of devices included in this category are used to measure glucose. In addition, many other analytes of clinical interest are measured with such devices.

Glucose Measurement. Clinically, POCT is most frequently used to measure glucose (see Chapter 25). The first glucose test strips were introduced more than 25 years ago, and now many millions of diabetics around the world use these strips in conjunction with a glucose meter to monitor their blood glucose level. These devices are biosensors since they all use an enzyme as the recognition agent, either glucose oxidase (GO), hexokinase (HK), or glucose dehydrogenase (GDH), with photometric (reflectance) or electrochemical detection.[53]

In general, all glucose strips are a form of what is called *thick-film* technology in that the film is composed of several layers each having a specific function. When blood is added to a strip, both water and glucose must pass into the film or analytical layer; for photometric systems erythrocytes must be excluded. These processes are achieved by what is called the separating layer that contains various components including glass fibers fleeces, membranes, and special latex formulations. In photometric systems, a spreading layer is important for the fast homogeneous distribution of the sample, whereas electrochemical strips use capillary fill systems. The support layer is usually a thin plastic material that in the case of reflectance-based strips may also have reflective properties. Additional reflectance properties have been achieved through the inclusion of substances such as titanium oxide, barium sulfate, and zinc oxide.

With systems that measure reflectance, the relationship between reflectance and the glucose concentration is described by the Kubelka-Munk equation:

$$C \alpha \frac{K}{S} = \frac{(1-R)^2}{2R}$$

where C is the analyte concentration, K is the absorption coefficient, S is the scattering coefficient, and R is the percent of reflectance. In practice, glucose strips are produced in large batches and, after extensive quality assurance procedures, each batch is given a code that is stored in a magnetic strip on the underside of each test strip. This code describes the performance of the batch, including the calibrating relationship between the photometric or electrochemical signal and the concentration of glucose.

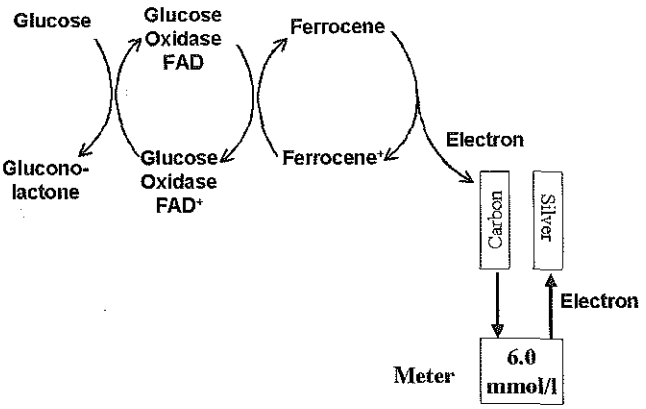

Figure 12-7 Schematic diagram of the reactions taking place in a MediSense electrochemical glucose strip. *(Modified from Henning TP, Cunningham TP. Biosensors for personal diabetes management. In Ramsay G ed, Commercial Biosensors. New York: John Wiley & Sons, 1998:3-46.)*

Since their introduction, there has been a steady stream of innovation in the development of glucose meters with the goal of making the devices smaller and easier to use with less risk of error and reducing interference from other compounds. The latter includes other reduction of substances, oxygen, and hematocrit. A major step in this development process was the use of ferrocene and its derivatives as immobilized mediators in the construction of an electrochemical glucose strip, the principles of which are shown in Figure 12-7.[30] The strip is composed of an Ag-AgCl reference electrode and a carbon-based active electrode, both manufactured using screen printing technology with the ferrocene or its derivatives contained in the printing ink. The sample is placed in the sample observation window and the hydrophilic layer serves to direct the sample over the reagent layer. The conversion of glucose is accompanied by the reduction of ferrocene and the release of electrons. The introduction of electrochemical technology has facilitated the production of smaller meters, nonwipe strips, less need to clean the instrument optics, and more rapid results. Some of these features are now available with photometric glucose meters.

Other Applications. Several immunosensor-based POCT devices have been developed that are capable of measuring a panel of analytes, such as cardiac markers,[4] allergy tests,[56] and fertility tests.[13] In these devices, a mixture of antibodies is immobilized at the origin, and complementary antibodies for the various analytes are immobilized at varying positions along the porous strip. In the case of drugs of abuse, devices are designed such that positive responses are only obtained if the concentration is above a precalibrated cut-off value.[15]

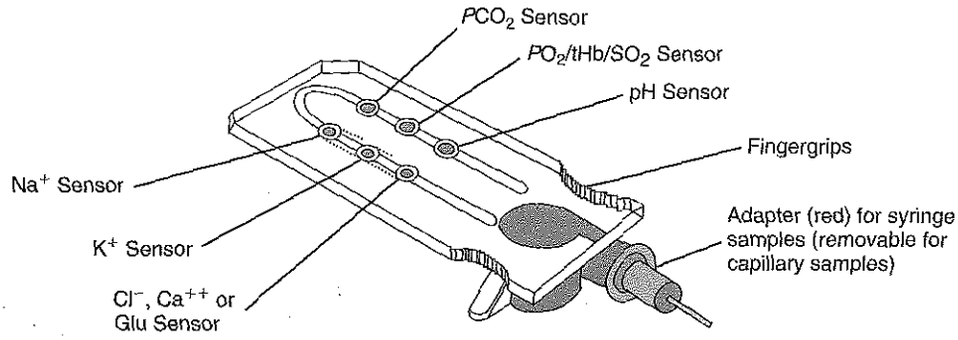

Figure 12-8 Schematic view of the measurement cassette for the Osmetech OPTI Critical Care Analyzer. *(Courtesy Osmetech, Roswell, GA.)*

In contrast to the thick-film technology described above, single-use sensors have also been constructed using *thin-film* technology, the most common commercial example being the i-STAT analyzer (see Chapter 10). This is a hand-held blood gas device, which measures electrolytes, glucose, creatinine, and certain coagulation parameters.[9,38] In thin-film sensors, electrodes are wafer structures constructed with thin metal oxide films using microfabrication techniques directly comparable with those used in the computer industry. The results are small, single-use cartridges containing an array of electrochemical sensors that operate in conjunction with a hand-held analyzer that can be used directly at the bedside.[32] Because the sensor layer is very thin, blood can permeate this layer quickly, and the sensor cartridge can be used immediately after it is unwrapped from its packing. This is an advantage over some thick-film sensors that require an equilibration or wet-up time before they can be used to measure blood samples.

Single-use devices for blood gas and other critical care measurements are also available through optical sensors or optodes[84] (see Chapters 4 and 27). The Osmetech OPTI Critical Care Analyzer (Figure 12-8) and the Radiometer NPT 7 are examples of this type of technology.[11,125] The advantages of optical systems compared with electrochemical transducers include the fact that they do not have to be calibrated to correct for electrode drift, and therefore the sensors are calibrated at the time of manufacture.[83]

A number of single-use, quantitative POCT devices are available that employ a cassette or cartridge design rather than lateral-flow strips. These include the Cholestech LDX system that uses a cassette that separates plasma from red cells after which the plasma reacts with pads of dry reagents for glucose or cholesterol or triglycerides and measurement of the absorbance in a small photometer.[24] Several cassette-based systems have been developed for measurement of hemoglobin, including the HemoCue. In this system, red cells are lysed in a minicuvet hemoglobin converted to methemoglobin and the methemoglobin measured at 570 nm; turbidity is corrected for by an additional measurement at 880 nm.[147]

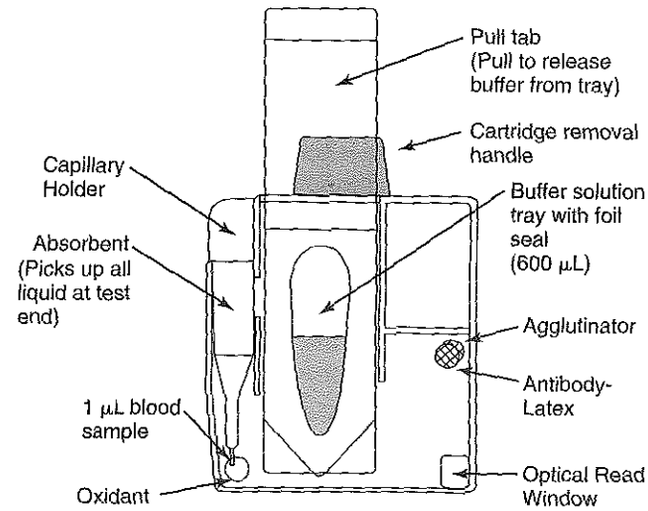

Figure 12-9 A schematic diagram of the Bayer DCA 2000 HbA_{1c} immunoassay cartridge. *(Courtesy Bayer HealthCare, Medfield, MA.)*

The Bayer DCA system is another example of a cartridge design but using a light-scattering immunoassay to measure glycated hemoglobin, together with a photometric assay for total hemoglobin. The cartridge is a relatively complex structure that contains antigen-coated latex particles, antibodies to HbA_{1C} and lysing reagents that are mixed following addition of the sample (Figure 12-9). Measurement takes place when the cartridge is placed into a temperature-controlled reader, and the analytical performance is sufficient for quantitative monitoring of diabetic control.[113] The size of the device allows it to be used in diabetic clinics where it can also be used for measurement of urinary albumin and creatinine.[23,108]

POCT devices for monitoring anticoagulant therapy have also been developed for use in clinics or by the patient at home.[104,105] These devices have been made possible by advances in optical detection techniques and the ability to miniaturize electromechanical devices. For example, early systems used magnets to detect the decrease in sample flow

or movement that results from the clotting process, but this required careful timing and a large blood sample. An alternative technology pumps a defined amount of the sample backward and forward through a narrow aperture. Optical sensors monitor the speed at which the sample moves and, as the clot forms, the speed decreases and when a predetermined level is reached, the instrument indicates the time.[2] Yet another approach also uses magnetism in the form of paramagnetic iron oxide particles that are included with the sample and induced to move by an oscillating magnetic field. When a clot is formed, the movement of the particles is restricted; this is detected by an infrared sensor, and the time taken to reach this state is an indication of the clotting time.[104]

Speckle detection technology has also been used to measure prothrombin time (PT), activated partial thromboplastin time (APTT), and activated clotting time (ACT). In this approach, the instrument contains an infrared light source that directs a coherent light beam onto the oscillating sample. The movement of the red cells in the blood results in the refraction of the light to produce an interference or "speckle" pattern that is recorded by the photodetector. This "speckle" pattern changes when the capillary flow slows as the sample clots. The time it takes for this to happen is a measure of the clotting time.[130] Other point-of-care devices that measure aspects of hemostasis and thrombosis include the Thromboelastograph and Sonoclot.[41a,145]

It should be noted that the sizes of some of the single-use, cartridge-based systems are comparable with certain of the bench top, multiple-use devices described later in this chapter. Examples of these analyzers, which are usually used in clinics and physician practices rather than at the bedside, are the Vision,[126] Stratus,[66] and Piccolo[124] devices, all of which incorporate onboard centrifugation. Other small analyzers that are used at point-of-care but require preliminary centrifugation of the sample include the Ortho-Clinical Diagnostics DT60, which uses the same dry-slide technology that is used in the larger, laboratory analyzers.[29]

Multiple-Use Cartridge and Bench Top Systems

Many of the POCT devices in this category are used for critical care testing in locations such as the intensive care unit, surgical suite, and emergency room. Some of these devices use thick-film sensors or electrodes in strips to measure glucose, lactate, and urea and use the same technology described above but differ in that the sensors are designed to be reusable. They are manufactured from thick films of paste and inks using screen printing techniques to produce individual or multiple sensors. In addition to measuring metabolites, these sensors are also used to measure blood gases and electrolytes.[31] The sensors have been incorporated with reagents and calibrators into a single cartridge or pack that is placed in the body of a small- to medium-sized, portable critical care analyzer (Figure 12-10). Each pack will measure a certain number of samples during a certain time

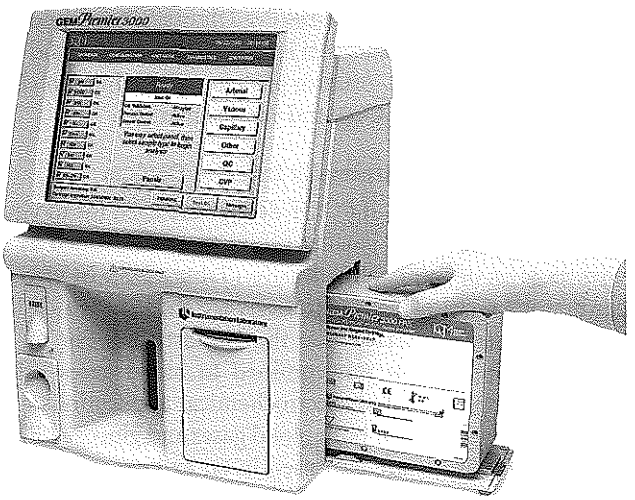

Figure 12-10 The GEM® Premier™ 3000 critical care analyzer. *(Courtesy Instrumentation Laboratory, Lexington, MA.)*

period, after which it is a relatively simple procedure to replace. This type of technology is available as the Instrumentation Laboratory GEM Premier,[59] the Radiometer ABL77,[81] and the Bayer Diagnostics Rapidpoint 400.[85]

Other key developments for devices include the development of liquid calibration systems that use a combination of aqueous base solutions and conductance measurements to calibrate the pH and PCO_2 electrodes, with oxygen being calibrated with an oxygen-free solution and room air.[92] In addition, automated QC packages are integrated into these analyzers that ensure that QC samples are analyzed at regular intervals. These comprise packs or bottles of QC material that are contained within the instrument and sampled at predetermined intervals with onboard software interpreting the results and generating alerts, if necessary. Such devices can even be remotely monitored and programmed to respond to problems on instruments located long distances from the central laboratory.[55]

Critical care POCT instruments are also available for measuring various hemoglobin species and performing CO-oximetry determinations. The latter relies upon multiwavelength spectrophotometry where light absorption by hemolyzed blood is measured at up to 60 or more wavelengths to determine the concentration of the five hemoglobin species.[14] One manufacturer has recently extended the multiwavelength spectrophotometry to measure bilirubin directly in whole blood.[123]

Bench top devices are also available to perform complete blood counts (CBC) using analytical principles similar to those used in laboratory-based devices.[33,35] In addition, single-use cartridge technology is being developed that will have the capability to offer full white cell differentiation. Immunoassay measurements are also now available in a compact device, for use in clinics and similar locations. The Innotrac Aio! is an example of such a device and uses

dry-coated reagents and time-resolved fluorescence for detection.[110] Results are produced in less than 20 minutes, and the assay menu includes C-reactive protein (CRP), human chorionic gonadotropin (hCG), and cardiac markers.[51]

In Vivo, Ex Vivo, or Minimally Invasive Devices

Although the majority of POCT devices are used for in vitro applications, there is a smaller group that is classified as in vivo, ex vivo, or minimally invasive (Table 12-3). In vivo or continuous monitoring applications are those in which the sensing device is inserted into the bloodstream. For many years, this application was confined to blood gases using optical technology,[148] but electrochemical applications also have been developed for both blood gases and glucose.[7] Electrochemical sensors are also used in an ex vivo application for the same parameters, the difference being that the sensors are actually external to the body but in a closed loop of blood that leaves the body and is then returned downstream from the sensing device.[152] The major application for minimally invasive devices is primarily glucose, such as the Gluco Watch Biographer device,[137] but devices for transcutaneous measurement of bilirubin are also now available,[122] although they are only suitable for screening purposes.

TABLE 12-3 Types of Ex Vivo, In Vitro, and Noninvasive Point-of-Care Testing Technology

Type of Technology	Analytical Principle	Analytes
Ex vivo	Optical fluorescence	pH, blood gases
	Electrochemistry	pH, blood gases, electrolytes, glucose
In vivo	Optical fluorescence	pH, blood gases
	Electrochemistry	Subcutaneous glucose
Noninvasive	Electrochemistry/ iontophoresis	Transcutaneous glucose
	Multiwavelength spectrophotometry	Bilirubin

Informatics and POCT

Most analytical devices used in clinical laboratories are directly linked or connected via an electronic interface to a laboratory information system (LIS). In this progression, many different informatic functions (see Chapter 18) are used, including the electronic transfer of data from the analyzers to the LIS and ultimately into a patient's electronic medical record. This provides healthcare professionals with quick, accurate, and appropriate access to the patient's medical history and information.

Considerable effort has been expended to incorporate these informatic processes into POCT devices. However, this has proved extremely difficult (Table 12-4), with early POCT devices lacking the hardware and software to acquire and store data and transfer it to an LIS. Consequently, analytical data were often not captured in a patient's medical record or had to be entered manually into an LIS with a major risk of transcription error. Thus important clinical information may be lost with the additional possibility of costly duplicate testing.[63] Newer POCT devices have addressed this problem by incorporating the prerequisite hardware and software into their design, but linking them to information management systems has proven problematic as each device had its own proprietary interface. The extent of this problem was highlighted by a survey of more than 500 United States hospitals conducted by the Enterprise Corporation for the American Association of Clinical Chemists in 1999 where it was found that only 15% of POCT data was sent to the LIS electronically, 18% entered manually, and 67% never reached the LIS. This lack of "connectivity" was identified as a major barrier to the effective deployment of POCT.[132]

To address the problem of a lack of connectivity in POCT instruments, a group of more than 30 companies involved in the POCT industry created a Connectivity Industry

TABLE 12-4 Informatic Issues With Present-Day Point-of-Care Testing Devices

Principle	Problem with POCT
Patient samples should be positively identified with the system	Strip devices do not carry identification (ID) and meters do not read IDs.
Operator access to the system should be password protected	This is not true of many hand-held meters
A hard copy of the record of the results, positively identified, should be generated	Many meters do not carry printers and results must be manually transcribed
Data should be stored in a local or remote database	This capability is not available on many devices
A log of events and of access should be maintained	This capability is not available on many devices

Modified from Jones R. Informatics and point-of-care testing. In: Price CP, Hicks JM, eds. Point-of-care testing. Washington DC: AACC Press, 1999: 175-95.

Consortium (CIC), that developed a set of seamless—"plug and play"—point-of-care communication standards. Adherence to these connectivity standards ensures that POCT devices meet critical user requirements, such as bidirectionality, device connection commonality, commercial software intraoperability, security, and QC and/or regulatory compliance. The design of the standards was based on (1) the use of a proven architecture and notation, (2) the use of existing standards and architectural patterns wherever possible, (3) a focus on services that would enable software intraoperability and add value to overall functionality, and (4) a reduction in the complexity of device communications.

Description of Connectivity Standards

The CIC connectivity standards are represented simply as the two interfaces between the POCT devices and information systems (Figure 12-11). The device interface passes patient results and QC information between the POCT instrument and devices, such as docking stations, concentrators, terminal servers, and point-of-care data managers. The latter have to be linked to a variety of information systems via the observation reporting interface or electronic data interface, for transmission of ordering information and patient results.

The connectivity standard was approved by the National Committee for Clinical Laboratory Standards (NCCLS) in 2001 as the POCT1-A standard.[100] Essentially, if a POCT device incorporates this standard, it should easily be able to communicate with laboratory and hospital information management systems, allowing exchange of data and information in a standardized format irrespective of vendor, location, or interface.

Benefits of POCT Connectivity

The full informatic benefits of connectivity may be some years away since the standards are only likely to be included in new products. However, pressure from laboratory scientists and users should encourage its adoption just as it helped with the formation of the CIC. At this stage, one of the most important benefits of connectivity will be to facilitate the transfer and capture of patient POCT and quality-related data into permanent medical records.[22] Other destinations for point-of-care data include the bedside monitors and clinical information systems that reside in critical care units. These systems integrate data from various sources, including vital signs and diagnostic results. In conjunction with clinical guidelines and expert systems, they can produce critical care maps used in the management of the critically ill patient.[47] Integration of POCT data with other clinical information is now quite commonly seen in disease management systems supporting the care of patients with chronic diseases, such as diabetes mellitus and hyperlipidemia. In the case of diabetes mellitus, the data manager serves to maintain a record of the blood glucose results and any other observations that the patient wishes to record to bring to the attention of the clinician at the next clinic visit. This record is then used to help patients with the management of their own disease. In the case of hyperlipidemia, the data may be fed into an algorithm together with other observations to calculate a risk score that is then used by the patient and his

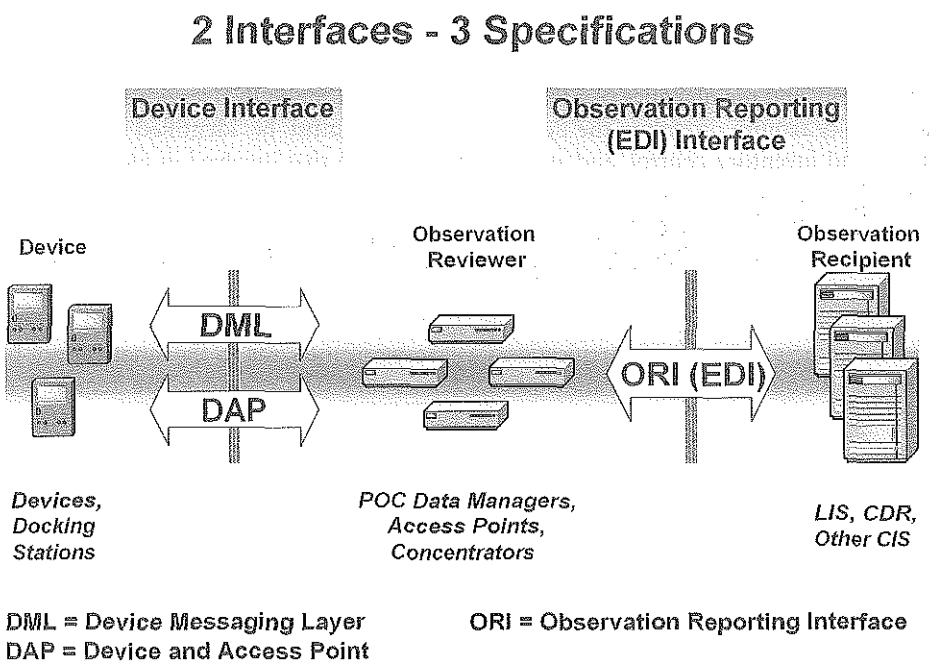

Figure 12-11 Schematic diagram of the interfaces between POCT devices and information systems. *(Modified from National Committee for Clinical Laboratory Standards: Point-of-Care Connectivity; Approved Standard. NCCLS Document POCT1-A. Wayne, PA. National Council for Clinical Laboratory Standards, 2001.)*

or her clinician to identify life style, dietary, and therapy changes, together with the expected outcomes (e.g., reduced risk of cardiovascular disease).

Innovations in the area of POCT quality will also be assisted by being able to easily link devices to networks and to those who are ultimately responsible for the device. Several manufacturers of POCT devices now provide software to allow central laboratories to monitor their instruments in remote locations. Currently, these packages are primarily in the critical care testing area, such as blood gases and related parameters, but with easier access to interfacing, it is likely that this type of software will be available for a wider range of devices. In conjunction with network technology, remote control software not only allows monitoring of the performance of the device but also enables those responsible for the instrument to carry out some service procedures or even shut the instrument down completely if required. Such software can manage a large number of devices that may be geographically dispersed and, by reducing the necessity to physically visit each device, it can result in significant staff savings.[55]

Although the need to have a permanent record of patient data is the most important benefit of connectivity for many laboratory scientists, others might place more emphasis on the requirement for accurate financial accounting of POCT. This would certainly be applicable in those countries where diagnostic testing has to be charged to the patient or their insurer. Easier connectivity of POCT data to accounting or billing systems will help prevent the obvious financial consequences of uncharged testing.

IMPLEMENTATION AND MANAGEMENT CONSIDERATIONS

Implementation, management, and maintenance of a POCT service in a healthcare facility require providing the necessary planning, oversight, and inventory control, and assuring the reliability of the results through adequate training and QC. Consequently a number of factors must be considered including (1) establishing need; (2) organizing and implementing of a coordination committee; (3) establishing a POCT testing policy and accountability; (4) procuring equipment and its evaluation; (5) training and certification of operators, establishing a QC, quality assurance, and audit policy; (6) ensuring documentation; (7) establishing an accreditation and regulation of POCT policy.

Establishment of Need

As with laboratory testing in general, the decision to implement a POCT service requires (1) establishment of need, (2) consideration of the clinical, operational, and economic benefits, and (3) the costs involved.*

*References 68, 79, 87, 95, 109, 118.

BOX 12-4 Assessing the Need for a Point-of-Care Testing Service

Which tests are required?
What is the TAT required?
What clinical question is being asked when requesting this test?
What clinical decision is likely to be made upon receipt of the result?
What action is likely to be taken upon receipt of the result?
What outcome should be expected from the action taken?
Why isn't the laboratory able to deliver the required service?
Will POCT provide the required accuracy and precision of result?
Is there staff available to perform the test?
Are there adequate facilities to perform the test and store the equipment and reagents?
Will you abide by the organizations POCT policy?
Are there operational benefits to this POCT strategy?
Are there economic benefits to this POCT strategy?
Will a change in practice be required to deliver these benefits?
Is it feasible to deliver the changes in practice that might be required?

Addressing the questions listed in Box 12-4 is useful for establishing the requirement for a POCT service. Answering them will help identify the test itself but should also explain why the current service is not meeting the needs of the patient or the clinician. Specifically, establishing the need for a POCT service should identify what benefits are likely to accrue to the patient and/or the healthcare provider by introducing a more rapid service. An economic assessment of the costs of delivering the current service and the costs associated with the POCT service should also be conducted. The benefits must be identified and accounted for in a way similar to that involved in identifying the cost of other elements of the health service. However, it is important in such an exercise to ensure that the costs associated with the benefits are recognized in terms of those that will redirect resources, as against those that may be more associated with an improved quality of care and ultimately quality of life. Some of the costs in the latter cannot be readily leveraged, and therefore resources are required to fund the POCT service. This part of the exercise is extremely useful as it often identifies the changes in practice that are required to release the resources to fund the new service and the potential difficulties associated with achieving such a change.

A risk assessment should also be conducted that will focus primarily on the procedures and processes that have to be put in place to ensure the maintenance of a high quality of service.[73] Issues of concern include (1) robustness of the POCT device, (2) quality of the results produced, (3) competence of the operator of the device, (4) effectiveness of the process for transmission of the results to the caregiver, (5) competence of the caregiver to interpret the results provided,

(6) procedures in place to ensure that an accurate record of the results is kept, (7) identification of what practice changes may have to be made to deliver the benefits that have been identified, (8) how the staff will be retrained if appropriate, and (9) how the changes in practice will be implemented.[69,102,121,127,146]

Organization and Implementation of a Coordination Committee

When organizing and implementing POCT service, it is important to consult with all of the parties involved in delivering such a service. This can be best achieved by establishing a POCT coordinating committee. Such a committee is then charged with managing the whole process of delivering a high quality POCT service. Membership of the committee should include representatives of those who use the service and those that deliver the service, together with a representative of the organization's management team. The users will include physicians, nurses, other healthcare providers, and maybe even a patient. The providers should include at least one representative from the laboratory and those involved in the use of other diagnostic and therapy equipment close to the patient (e.g., respiratory measurement technologists and nurses). Typically a laboratory professional will chair such a committee because it is the laboratory that will provide the necessary backup if there is a service failure; furthermore the laboratory professional will have had training and expertise with the analytical issues that are likely to arise. For many reasons, the committee should report to the medical director. The committee should then designate members who will take the responsibility for overseeing the training and accreditation of all POCT operators and also for QC and quality assurance. The work of the committee should be governed by the organization's policy on POCT.

POCT Policy and Accountability

Implementation of a POCT service requires a POCT policy that establishes all of the procedures required to ensure the delivery of a high quality service, together with the responsibility and accountability of all staff associated with the POCT. This may be (1) part of the organization's total quality management system,[60] (2) part of its *clinical governance policy,*[42] and (3) required for accreditation purposes.[17,18] The elements of a POCT policy are listed in Box 12-5.

Equipment Procurement and Evaluation

After establishing the requirement, coordination committee, and policy, the next stage in the process is equipment procurement. This involves first identifying candidate POCT equipment having the prerequisite analytical and operational capabilities to meet the clinical requirements of a POCT service. As discussed in Chapter 15, the performance characteristics of these devices are then obtained and compared. These include parameters such as accuracy, precision, TAT, calibration frequency, potential interferants, calibrator and reagent stability, variation in different lot numbers of reagents and calibrators, and QC requirements. In addition, operational requirements made of the operator also have to be identified, and the potential for operator error (including delayed addition of the sample and use of an incorrect sample volume) determined. Independent validation of these analytical and operational characteristics can be obtained from (1) the manufacturer; (2) published evaluations performed by agencies such as the Medical Devices Agency in the United Kingdom; and (3) reports in the peer-reviewed literature. When reviewing performance data, particular attention should be paid to the precision and accuracy of measurement, including the concordance between the results produced by the POCT device and by a routine laboratory method, because patients are likely to be managed using both analytical systems. This concordance may be difficult to assess, and it may be necessary to seek endorsements from current users of the systems and possibly conduct some form of internal trial. Evaluation of

analytical performance will be addressed in Chapter 14 and in the NCCLS protocol.[99]

An economic assessment of the equipment, including the cost of consumables and servicing, should also be made. This is likely to be a comparative exercise between the various point-of-care systems under consideration. Any comparison of costs with the laboratory service will only be highlighting the cost per test, which, as stated earlier, will not give an accurate assessment of the cost utility of the system. However, it is helpful at this point to have a good assessment of the relative staff costs associated with different systems because these are likely to be key features in the decision-making process. It is likely that the chosen system will be operated by staff already performing a wide range of duties involving the care of patients, and therefore the amount of time required to operate the device may be critical.

After the comparison data have been obtained, tabulated, and interpreted, a POCT device is selected. It is then recommended that the laboratory professional conduct a short evaluation of the equipment to gain familiarization with the system. This evaluation will help to determine the content of the training routine that will have to be subsequently developed and if troubleshooting of problems is required. Such an evaluation should document the concordance between the results generated with the device and those provided by the laboratory. All of this information should then be recorded in a logbook associated with the equipment. In addition, the organization may wish to undertake some form of safety check, give the device some form of local code, and enter the code into the local equipment register.

Training and Certification

The confidence of the clinician, the caregiver, and the patient in the results generated by a POCT device depends heavily on the robustness of the instrument and the competence of the operator, given that it has already been shown to meet the analytical requirements of the clinical setting. Many of the agencies involved in the regulation of healthcare delivery now require that all personnel associated with the delivery of diagnostic results demonstrate their competence through a process of regulation, and this applies equally to POCT personnel. Typically, those healthcare professionals involved in POCT will not have received training in the use of analytical devices as part of their core professional training but may be called upon to operate a number of complex pieces of equipment.

The elements of a training program are listed in Box 12-6. In practice such a program is tailored to suit the needs of the individual and the organization.[134] These may include formal presentation to groups, or on a one-to-one basis, self-directed learning using agreed documentation or computer-aided learning. For example, several of the current models of blood gas and electrolyte analyzers have onboard computer-aided training modules. Whatever the training strategy employed, it is important to document the satisfactory completion of training and that the individual has been tested and found competent with a combination of questions concerned with understanding and practical demonstration of the skills gained. The latter can be achieved by performing tests on a series of QC materials and repeat testing of samples that have recently been analyzed (parallel testing). Finally the operator should be observed through the whole procedure involved in the POCT on a minimum of three occasions.

BOX 12-6 The Main Elements of a Point-of-Care Testing Training Program

Understanding the context of the test—pathophysiological context
- Clinical requirement for the test
- Action taken on basis of result
- Nature of test and method used

Patient preparation required—relevance of diurnal variation
- Relevance of drug therapy

Sample requirement and specimen collection
Preparation of analytical device—machine and/or consumables
Performance of test
Performance of quality control
Documentation of test result and quality control result
Reporting of test result to appropriate personnel
Interpretation of result and sources of advice
Health and safety issues (e.g., disposal of sample and test device, cleaning of machine and test area)

Competence on a long-term basis is maintained through regular practice of skills and continuing education, and it is important to build these features into any education and training program. Regular review of performance in QC and quality assurance programs will provide a means of overseeing the competence of operators. However, this is not always sufficient, particularly when operators are employed on irregular shifts or may not always be called upon to perform POCT. In this latter situation, it may be necessary to create specific arrangements for individuals to undertake tests on QC material. The error log may also highlight when problems are arising. However, the most important thing is to encourage an open approach to the assessment of competence so that operators themselves seek help if they believe that problems are occurring. Such an open approach should be supported with audit and performance review meetings where problems are aired and developments discussed. The regular assessment of competence should be built into a formal program for recertification that will be a requirement of most accreditation programs.

Quality Control, Quality Assurance, and Audit

QC and quality assurance programs provide a formal means of monitoring the quality of a service (see Chapter 19). The internal QC program is a relatively short-term view and typically compares the current performance with that of the

last time the analysis was made. External quality assurance on the other hand takes a longer-term view and in some respects addresses other issues surrounding the quality of the result. Thus quality assurance compares the testing performance of different sites and/or different pieces of equipment or methods.[16,145] An audit is a more retrospective form of analysis of performance and, furthermore, can take a more holistic view of the whole process. However, the foundation to ensuring good quality remains a successful training and certification scheme.

Classically, quantitative internal QC involves the analysis of a sample for which the analyte concentration is known, either because the material has been analyzed on many occasions and the distribution of results documented, or because it has been analyzed independently and the mean and range of results quoted for the method used. The essence of using the internal QC material is to establish the interval of results that is acceptable; the current analytical result is compared with the interval of results deemed to be acceptable (see Chapter 16). The result must then be documented, usually graphically, because it shows the conformity of results and any trends in results that may be occurring. The major aim is to use a means of documentation that ensures that comparative performance is assessed.

There are several challenges to the classical approach with POCT. The first concerns the frequency of testing—should a QC sample be analyzed every time that (1) a sample is analyzed, (2) a new operator uses the system, (3) a new lot number of reagents is used, or (4) the system is recalibrated? There is no consistent agreement on the correct approach, and one probably has to be guided by the reproducibility and overall analytical performance of the system and local circumstances, such as the number and competence of the operators, together with the frequency with which the system is used. For a bench top and/or multitest analyzer, at least one QC sample should be run a minimum of once per shift—three times a day. Some critical care analyzers can be programmed to perform a QC check at intervals set by those responsible for the device.

For single-use POCT disposable devices, the above strategy cannot completely monitor the quality of the test system.[111,151] For example, when conventional QC material is analyzed on a unit-use or single-test POCT system, only that testing unit is monitored. Thus it is impossible to test every unit with control material because by definition these are single-test systems and one cannot analyze both control material and a patient sample with the single unit. Under these circumstances, there is greater dependence placed on the manufacturing reproducibility of the devices to ensure a good quality service. A 2002 NCCLS guideline reports quality management procedures for unit-use testing both from a manufacturer's and a user's perspective.[101]

In the case of the user, some may wish to continue with a QC testing strategy that is similar to that for multiuse devices, namely analyze a minimum of one QC sample per run during each shift. If testing is infrequent, then another approach would be to analyze a QC sample whenever there is a change to the testing system, such as a different batch of testing materials or a different operator.[98] There are also other QC approaches, but many do not test the whole process. For example, the use of a plastic surrogate reflectance pad as a QC sample will only test the performance of the reflectance meter and does not test the process of sample addition, etc. Similarly the same forms of electronic internal QC, used for example with the i-STAT cassette system, also do not test the sampling technique but simply the functionality of the cassette and the docking station.[151]

External quality assurance or proficiency testing is a systematic approach to QC monitoring in which standardized samples are analyzed by one or more laboratories to determine the capability of each participant. In this approach, the operator has no knowledge of the analyte concentration, and therefore it is considered closer to a "real testing situation." The results are transmitted to a central authority, who then prepares a report and returns a copy to each participating laboratory. The report will identify the range of results obtained for the complete group of participants and may be classified according to the different methods used by participants in the scheme. The scheme may encompass both laboratory and POCT users, which gives an opportunity to compare results with laboratory-based methods. In practice, external quality assurance or proficiency testing is used in POCT to determine and document long-term performance and the concordance of results between the POCT service and an organization's central laboratory. It is also possible to operate an external quality assurance scheme within a hospital or organizational setting; such a scheme would typically be run by qualified laboratory personnel. This provides the opportunity to compare the results being reported by both the laboratory and other POCT sites within the same organization. This can be important when patients are managed in several departments—or when machines break down and samples are taken to other sites for testing. When deteriorating or poor performance is identified in one of these schemes, it is important to document the problem, and then provide and document a solution. It may be necessary as part of this exercise to review some of the patient's notes to ensure that incorrect results have not been reported and inappropriate clinical actions taken. In addition, if the solution highlights a vulnerable feature of the process overall or for one particular operator then a process of retraining must be instituted.

An example of data from an external quality assurance scheme for POCT is shown in Figure 12-12. Such schemes are run on a national and international basis, and some Web site schemes are listed in references.[25,141,149]

Maintenance and Inventory Control

The implementation and maintenance of a POCT service require that a supply of devices be maintained at all times and a formal program for doing so employed. The key points

in this process are to (1) adhere to the recommended storage conditions, (2) be aware of the stated shelf life of the consumables, and (3) ensure that stocks are released in time for any preanalytical preparation to be accommodated (e.g., thawing). When multiple sites are using the same materials, then a central purchasing, supply and inventory control system should be put in place—not only to gain the benefit from bulk purchasing, but also to ensure that individual systems are not supplied unknowingly with different batches of consumables.

The complexity in the maintenance of reusable devices will vary from system to system, but clear guidelines will be available from the manufacturer and should be adhered to rigorously. Issues that usually require particular vigilance include expiration dates, bio-contamination, electrical safety, maintenance of optics, and inadvertent use of inappropriate consumables.

Documentation

The documentation of all aspects of a POCT service has been a major issue for many years, compounded by the fact that often the storage of data in laboratory and hospital information systems has been limited and often inconsistent. Thus it is critically important to keep an accurate record of the test request, the result, and the action taken as an absolute minimum. Some of the issues concerning documentation are now being resolved with the advent of the patient electronic record, electronic requesting, and better connectivity of POCT instrumentation to information systems and the patient record (see earlier discussion). The

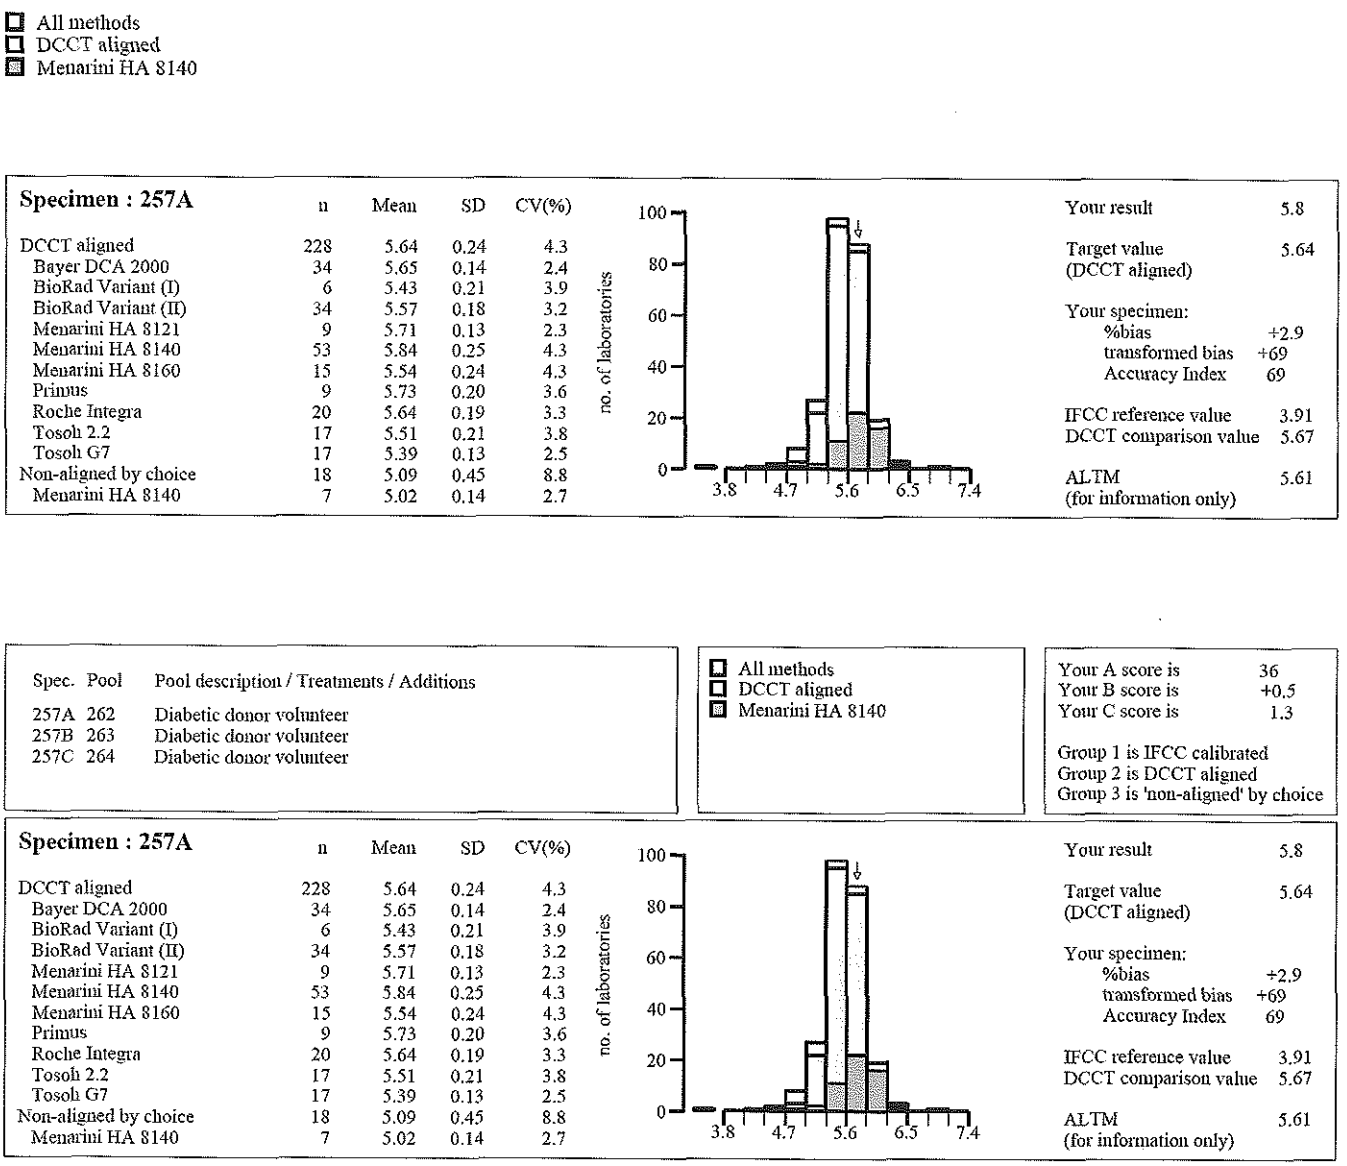

Figure 12-12 Extract of data from Distribution 257 of the UK NEQAS for Glycated Hemoglobin, May 2003. *(Courtesy Dr. J. Middle, UK NEQAS.)*

documentation should extend from the standard operating procedure(s) for the POCT systems to records of training and certification of operators, internal QC and quality assurance, together with error logs and any corrective action taken.

Accreditation and Regulation of POCT

The features of the organization and management of POCT described above are the same as those for the accreditation of any diagnostic services.[17,18] Accreditation of POCT should be part of the overall accreditation of laboratory medicine services, or indeed as part of the accreditation of the full clinical service, as has been the case in many countries, including the United States and the United Kingdom for a number of years. Thus the Clinical Laboratory Improvement Amendments of 1988 (CLIA) legislation in the United States stipulates that all POCT must meet certain minimum standards.[142,143] In the United States, the Centers for Medicare and Medicaid Services, the Joint Commission on Accreditation of Healthcare Organizations, and the College of American Pathologists are responsible for inspecting sites and each is committed to ensuring compliance with testing regulations for POCT.[37]

FUTURE OF POCT

We believe that the three key drivers for expansion of POCT services in the future will be (1) changes in the way healthcare is provided, (2) patient's needs and expectations, and (3) technological innovation. Currently the trends in the manner that clinical care is being delivered are completely opposite to the way in which diagnostic testing services are moving. For example, although laboratories are being consolidated with emphasis on more efficient and productive testing facilities, patient care is being moved closer to the patient and away from the larger hospital unit (Figure 12-13). This will effectively lead to either an increase in the logistics effort required to support the TATs expected by clinicians and patients, or a dramatic increase in the volume of POCT.

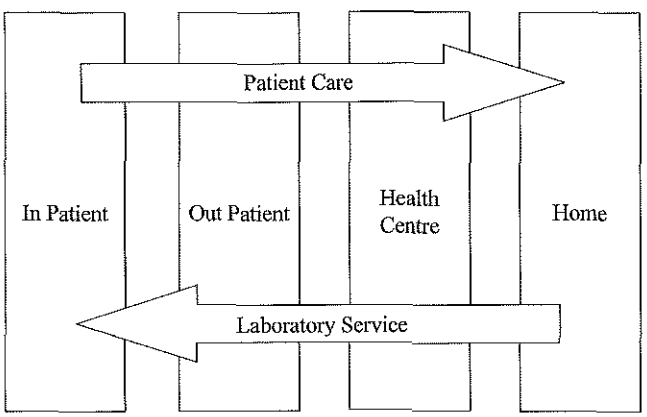

Figure 12-13 Diagram of the trends in healthcare today that include devolution of patient care to the primary care sector while laboratory medicine is consolidating in the "opposite direction."

Patient expectations are increasing and will drive the trend toward more patient-focused style of care with fewer clinic visits, shorter waiting times, and an expectation of better care. POCT has been shown to be capable of shorter "lengths of stay" and in many cases improved health outcomes. As health service decision makers (both purchasers and providers) realize that it is possible to achieve lower "costs per patient episode" with the use of POCT, more of the effort will be put into this testing modality. So what will facilitate this revolution? The answer lies in the new technology—both in terms of the new delivery platforms that are being developed and also in the discovery of new markers.

There are now considerable efforts being made to develop and manufacture miniaturized analytical devices (see Chapters 4 and 10) that will enable faster analytical times to be achieved, with smaller sample requirements. There are now several examples in the field of microfabricated devices that have been shown to meet these aspirations.[77,78] In the future, continued technological advances will result in even smaller devices that can be tailored for a large number of analytes and that are very simple to operate.

Noninvasive testing has promised much, and over the past decade, there is now evidence of some success in this area. The majority of work has been performed on a range of imaging techniques that seek a signature of the molecule of interest (e.g., glucose from among the many signatures of the extracellular and tissue matrix[70,90,97,112]). Alternative approaches have sought to access the extracellular fluid space or to sample the extracellular fluid directly, such as with the Glucowatch.[137]

The three areas of testing that will increase significantly are testing for infectious agents using molecular based techniques, testing for the predisposition to disease, and assessing an individual's response profile toward a new drug. In the case of all three scenarios, the key to having a POCT is the need for early decision making to implement therapy (or life style change), together with the need for patient counseling. There is clearly now the technology available to detect any form of biological entity at the point-of-care, including very rapid analysis of deoxyribonucleic acid (DNA) from saliva samples.[43] However, there are clearly many ethical issues surrounding the analysis for genetic predisposition and tests for certain infectious diseases.

An area of great interest, however, lies in the field of pharmacogenomics (see Chapter 43)—although it is not yet clear whether it will be the proteomic or the genomic markers that will predominate. It is already acknowledged that each person responds to or metabolizes drugs differently. Tailoring drug therapy to achieve an individualized optimal level is preferable—and from the foregoing examples it is clear that to be able to perform that optimization at the time of the clinic visit reduces the need for future clinic

visits, improves compliance, and meets with both patient's and caregiver's approval. Individualization of drug therapy has already been shown to be effective for the management of diabetes, anticoagulation status, hypertension, anticonvulsant therapy, azothioprine treatment, Herceptin treatment, and many others, although POCT has not been implemented on a routine basis in many of these clinical conditions.

In closing, it is difficult to predict the role of POCT in self-testing as part of a wellness program. For example, the level of self-testing for cholesterol has not reached the predictions that were made several years ago—and the reasons for this are not entirely clear. If testing for some analytes remains restricted as is the case in some countries today, then it is possible that individuals will seek the tests from a POCT source. Examples include tests for cancers such as prostate, bladder, and colon that have attained a high level of media coverage in recent years.

Introduction to Laboratory Medicine and Evidence-Based Laboratory Medicine

Christopher P. Price, Ph.D.,
Patrick M.M. Bossuyt, Ph.D.,
and David E. Bruns, M.D.

This chapter introduces the section "Principles of Laboratory Medicine." In the beginning of the chapter, we consider the meaning of the term "laboratory medicine" and the relationships among clinical chemistry, laboratory medicine, and evidence-based laboratory medicine. The remainder of the chapter focuses on key concepts of evidence-based laboratory medicine and thus provides a transition from the chemical principles presented in the preceding chapters to the more clinical focus of the following six chapters in this section. Key chapter topics are diagnostic accuracy of tests, clinical outcomes studies, economic evaluations of medical tests, systematic reviews of diagnostic tests, clinical practice guidelines, and clinical audit. The principles provide a foundation for the rational and appropriate use of diagnostic tests.

CONCEPTS, DEFINITIONS, AND RELATIONSHIPS

In this section, laboratory medicine and clinical chemistry are defined. The relationships between these two fields of endeavor are discussed.

What Is Laboratory Medicine?

The term "laboratory medicine" refers to the discipline involved in the selection, provision, and interpretation of diagnostic testing that uses primarily samples from patients. The field includes research, administration, and teaching activities and clinical service. Testing in laboratory medicine may be directed at (a) *confirming* a clinical suspicion (which could include *making* a diagnosis), (b) *excluding* a diagnosis, (c) assisting in the *selection, optimization, and monitoring* of treatment, (d) providing a *prognosis*, or (e) *screening* for disease in the absence of clinical signs or symptoms. Testing is also used to establish and monitor the severity of a physiological disturbance.

The field of laboratory medicine includes clinical chemistry and molecular diagnostics and their traditional subdisciplines (such as toxicology and drug monitoring, endocrine and organ-function testing, "biochemical" and "molecular" genetics, etc.) and areas such as microbiology, hematology, hemostasis and thrombosis, blood banking (transfusion medicine), immunology, and identity testing. In some parts of the world, laboratory medicine also encompasses cytology and anatomical pathology (histopathology). The analytical components of these specialties are delivered from central laboratories or through a more distributed type of service (point-of-care testing [POCT]) or both.

Data management and interpretation (including laboratory informatics) are key aspects of the laboratory medicine service, as are activities concerned with maintaining quality

(e.g., quality control and proficiency testing, audit, benchmarking, and clinical governance).

Clinical Chemistry and Laboratory Medicine

The ties between clinical chemistry (or clinical biochemistry) and other areas of laboratory medicine have deep roots. Individuals working primarily in the area of clinical chemistry have developed tools and methods that have become part of the fabric of laboratory medicine. Examples include the theory and practice of reference intervals (Chapter 16), the use of both (internal) quality control and proficiency testing (Chapter 19), the introduction of automation in the clinical laboratory (Chapter 11), and concepts of diagnostic testing, which are discussed in this and other sections of the book. From the physician's and the patient's perspective, there is no distinction between the specialties and invariably the repertoire of more than one specialty will be called upon when making a clinical decision (e.g., in the diagnosis and management of renal failure, or in the management of the patient in intensive care).

The boundaries between clinical chemistry and other areas of laboratory medicine are not always distinct. In many institutions, clinical chemists initiate and direct activities, such as laboratory informatics and POCT. In some areas of the world, the term "clinical chemistry" has long been used to include laboratory areas such as hemostasis, thrombosis testing, immunology testing, and parts of hematology that in the United States are not considered to be part of classical clinical chemistry.

Boundaries between and among the parts of the clinical laboratory have blurred further with the increasing emphasis on use of chemical and "molecular" testing. Molecular diagnostics testing has evolved beyond human genetic testing, an area in which clinical chemists have long been active. Now, clinical chemists in "molecular" laboratories contribute their expertise in laboratory medicine to infectious disease testing, cancer diagnostics, and identity testing, activities that were formerly associated almost solely with, respectively, clinical microbiology, hematology, and blood bank laboratories. Successful contribution to these areas requires an understanding of the principles of laboratory medicine and close collaboration with clinical microbiologists, hematologists, and others who have specialized expertise in those areas of laboratory medicine.

The relationship between laboratory medicine and the clinical chemist has evolved further with the advent of "core" laboratories. These laboratories, which provide all high-volume and emergency testing in many hospitals, depend on automation (see Chapter 11), informatics and computers (Chapter 18), and a high level of quality control and quality management (Chapter 19). Clinical chemists, who have long been active in these areas, have assumed increasing responsibility in core laboratories and thus have become more involved in areas such as hematology, coagulation, urinalysis, and even microbiology. Thus a new type of "clinical chemist" has emerged, and again the functions require a broader knowledge of laboratory medicine and greater collaboration with other specialists.

The close associations of clinical chemistry and laboratory medicine have been evident in other public ways. Most journals in the field of clinical chemistry publish papers in all of the areas of laboratory medicine. The subtitle of the journal *Clinical Chemistry* even includes the term "Laboratory Medicine." Moreover, the international association of clinical chemistry societies is now called the International Federation of Clinical Chemistry and Laboratory Medicine.

Clinical Chemistry, Laboratory Medicine, and Evidence-Based Laboratory Medicine

In this chapter, we review the new influences on clinical chemistry and laboratory medicine from the fields of clinical epidemiology and evidence-based medicine (EBM). Clinical epidemiologists have developed study designs to quantify the diagnostic accuracy of the tests developed in laboratory medicine, and study methods to evaluate the effect and value of laboratory testing in healthcare. Practitioners of EBM focus on use of the best available evidence from such well-designed studies in the care of individual patients. EBM rephrases problems in the clinical care of patients as structured clinical questions, looks for the available evidence, evaluates the quality of clinical studies, evaluates the clinical implications of the results, and provides tools to help clinicians optimally use those results in the care of individual patients.

EVIDENCE-BASED MEDICINE—WHAT IS IT?

This brief section contains a definition of EBM and describes its goals and key practices. Following this, evidence-based laboratory medicine will be addressed.

Definition and Goals of Evidence-Based Medicine

Among the definitions proposed for EBM, the foremost probably is "*the conscientious, judicious, and explicit use of the best evidence in making decisions about the care of individual patients.*"[81] The word *judicious* implies use of the skills of experienced clinicians to put the evidence in context, and to recognize patient individuality and preferences.[62] A goal of EBM is "*to incorporate the best evidence from clinical research into clinical decisions.*"[40] The word *best* implies the necessity for critical appraisal. The words *making decisions* indicate why the principles of EBM can, and must, be applied in laboratory medicine as laboratory medicine is one of the fundamental tools used in making decisions in the practice of medicine.

Since the introduction[29] of the term "evidence-based medicine" in 1991 by Gordon Guyatt (initially in an editorial in *ACP Journal Club* and in a supplement to *Annals of Internal Medicine*), volumes have been written on the topic. A PubMed search on January 2, 2005, for the term returned

16,421 articles. The papers address every area of medicine and activities such as disease management.[27] Compared with practitioners in many of these areas, workers in clinical laboratories were late in embracing the activities of EBM, but numerous studies are now influencing the practice of clinical chemistry and laboratory medicine.

The justifications for an evidence-based approach to medicine are founded on the constant requirement for information[72]; the constant addition of new information[63]; the poor quality of access to good information[1]; the decline in up-to-date knowledge and/or expertise with advancing years of an individual clinician's practice[18]; the limited time available to spend with the patient, let alone read the literature[82]; and the variability in individual patients' values and preferences. To this one might add, particularly in relation to laboratory medicine, (1) the limited number and poor quality of studies linking test results to patient benefits,[59] (2) the poor perception of the value of diagnostic tests, (3) the ever-increasing demand for tests, and (4) the disconnected approach to resource allocation (reimbursement) in laboratory medicine, "silo budgeting," which addresses only laboratory costs without consideration of benefit outside the laboratory, thus forcing decisions to save expense in the laboratory with insufficient attention to the needs of patients, their caregivers, and the payers.

The Practice of Evidence-Based Medicine

Guyatt and colleagues[41] summarized the practice of EBM as follows:

> "An evidence-based practitioner must understand the patient's circumstances or predicament; identify knowledge gaps and frame questions to fill those gaps; conduct an efficient literature search; critically appraise the research evidence; and apply that evidence to patient care."

The efficient practice of EBM requires:

- A knowledge of the *clinical process* and conversion of a clinical goal into an answerable question
- Facility to generate and critically appraise information to generate knowledge
- A critically appraised knowledge resource
- Ability to use the knowledge resource
- A means of accessing and delivering the knowledge resource
- A framework of clinical and economic accountability
- A framework of quality management

The identification of a clinical goal provides the foundation of the service provided by the healthcare professional. In the area of laboratory medicine, as described later in this chapter, the goal can be expressed in terms of answering a clinical question; appropriate laboratory investigations help to answer the question.[75] Knowledge of the characteristics of these investigations is needed to decide which test to use, when to use it, and how to interpret the results.

Finding and appraising knowledge that is relevant to the question requires awareness of the information resources available, ready access to them, and an ability to critically appraise the relevance of the available data.

A knowledge resource in the form of systematic reviews (see later in this chapter) should provide the critically reviewed evidence of the efficacy, benefits, limitations, and risks from using a test, intervention, or device. Access has classically been through scientific journals and textbooks, and electronic communication of various sorts (including textbooks and journals) is making access faster and more up to date.

Knowledge on the use of a test or intervention ultimately has to be placed in the context of a clinical and economic accountability framework and ensuring the highest quality and lowest risk to patients. Clinical audit is a key element of meeting this objective.

EVIDENCE-BASED MEDICINE AND LABORATORY MEDICINE

When a patient has symptoms or signs of a health problem, the clinician establishes hypotheses about their etiology. Competing hypotheses must be resolved. After decisions are made about the nature of the condition, the process of care may then involve further decisions depending on the nature of the problem or disease. The services of laboratory medicine are one of the tools at the disposal of the clinician to answer the questions posed by the hypothesis generation and to help make decisions.[79]

The tools provided by laboratory medicine are called *diagnostic* tests, but it must be understood that tests are used far more broadly than in making a diagnosis. As mentioned above and discussed below, they are also used in making a prognosis, excluding a diagnosis, monitoring a treatment or disease process, and screening for disease. Thus the word "diagnostic" is used (often unknowingly) in the formal sense of a diagnostic system, the quotidian example of which is the daily weather forecast.

What Is Evidence-Based Laboratory Medicine?

Evidence-based laboratory medicine is simply the application of principles and techniques of EBM to laboratory medicine. A clinician requesting an investigation has a question and must make a decision. The clinician hopes that the test result will help to answer the question and assist in making the decision. Thus a definition of evidence-based laboratory medicine could be "*the conscientious, judicious, and explicit use of best evidence in the use of laboratory medicine investigations for assisting in decision-making about the care of individual patients.*" It might also be expressed more directly in terms of health outcomes as "*ensuring that the best evidence on testing is made available and the clinician is assisted in using the best evidence to ensure that the best decisions are made about the care of individual patients and lead to increased probability of improved health outcomes.*" As discussed later, outcomes can be clinical, operational, and/or economic.[76]

Types of Diagnostic Questions Addressed in Laboratory Medicine

The decision-making process involves one of four scenarios typified by these questions (Figure 13-1):

- What is the diagnosis?
- Can another diagnosis be ruled out?
- What is this patient's prognosis?
- How is the patient doing?

In the first case, a diagnosis is being sought, with a diagnostic conclusion leading to a decision and some form of action, which often involves an intervention; the intention is that the cascade for diagnostic question through result, decision, and action should lead to an improved outcome. An example of this scenario would be when a test for acetaminophen indicates that there has been ingestion of an excessive amount of drug, and the administration of *N*-acetylcysteine reduces the risk of a fatal outcome. The measurement of acetaminophen in this scenario is referred to as a "rule-in test."

In the second scenario, the test result excludes a diagnosis; this is referred to as a "rule-out test." The actions resulting from excluding a diagnosis will invariably involve the evaluation or creation of another hypothesis. When a patient is admitted with atypical chest pain and acute myocardial infarction is suspected, the measurement of troponin may be used to rule out (or rule in) acute myocardial necrosis.

The third use of an investigation is for prognosis, which may be considered as the assessment of risk, and complements the diagnostic application. For example, the measurement of human immunodeficiency virus (HIV) viral load following initial diagnosis of HIV infection predicts the time interval before immune collapse if the condition is not treated.

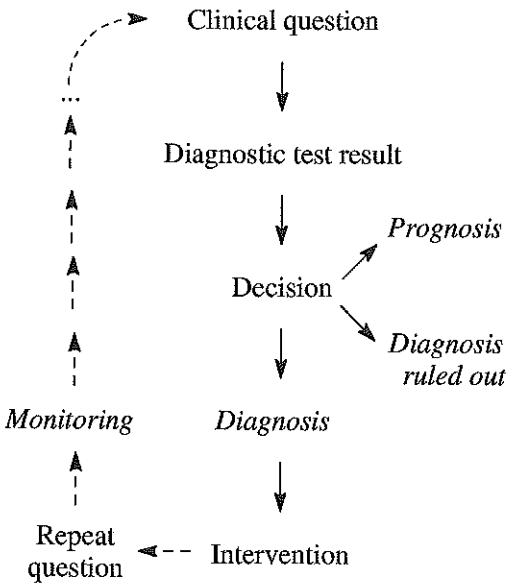

Figure 13-1 Schematic representation of four common decision-making steps in which the result of an investigation is involved.

The fourth broad use of a test result is concerned with patient management. In a patient with a chronic disease, the result may be used to select the type of intervention and assess the effectiveness of an intervention, and the action will be to change or continue the treatment. In women with metastatic breast cancer, the HER-2/*neu* status is used to assess the potential usefulness of Herceptin therapy. In a person with diabetes, hemoglobin (Hb) A_{1c} measurements are used to assess glycemic control and thus the effectiveness of therapy.

These scenarios illustrate the importance of identifying the triad of *question, decision, and action*. Identifying these three components proves to be critical in designing studies of utility or outcomes of testing (see later in this chapter and Chapter 15). They are also important in audit (see below) of the use of investigations both from the point of clinical governance (clinical accountability) and financial governance (controlling the test demand in the context of economic governance). The recognition of this triad has led to the definition of an *appropriate test request* as one in which there is a clear clinical question for which the result will provide an answer, enabling the clinician to make a decision and initiate some form of action leading to a health benefit for the patient.[75"] This benefit could be extended to the health provider and to society as a whole to encompass more directly the potential for economic benefit.

Examples of questions that specify the detail required to accurately qualify the use of a test result are given in Table 13-1. The criteria for a screening test have been established for many years; importantly one of the key criteria is that there must be valid treatment available. The clinical episode involves a series of diagnostic questions with binary responses[16]—a point illustrated in Table 13-1.

Test Results Alone Do Not Produce Clinical Outcomes

In most cases, testing is followed by an appropriate intervention to produce a desired outcome, particularly when the outcome is defined as improved morbidity or mortality. A test result alone may provide reassurance or an understanding of the origin of one's complaint, but usually these good outcomes require an intervention in the form of an explanation of the result in the context of the patient's symptoms. Thus it is difficult to design EBM studies that investigate the utility of the test in isolation. Thus most laboratory medicine research encompasses only test characteristics. This restricted research leads to a poor understanding and appreciation of the contribution that the test result makes to improved outcomes. In relation to certain scenarios it is possible to find valid study data, most particularly when the test result is being used to exclude a diagnosis. Thus in a randomized study of a rapid chest pain evaluation protocol, cardiac markers had a high negative predictive value in patients evaluated with chest pain. Testing led to fewer admissions to the coronary care unit, without adversely affecting morbidity and mortality.[68] Reducing the turn-

TABLE 13-1 Examples of Clinical Questions in Which a Laboratory Assessment May Be of Value, and the Associated Action and Potential Outcome (Benefit)

Test	Question	Result	Possible Action	Possible Outcome
Rule In				
B-type natriuretic peptide (BNP)	Is this breathless patient suffering from heart failure?	450 ng/L	Confirm with cardiac ultrasound, decide to admit and treat	Reduced symptoms, decreased morbidity and mortality
Troponin I (TnI)	Has this patient had a myocardial infarction?	7.2 μg/L	Decide to admit, intensity of care required, and treat	Decreased morbidity and mortality
TSH	Does this child have hypothyroidism?	12.2 mU/L	Treat with thyroxine	Decreased morbidity and mortality
Urine leukocyte esterase (LE) and nitrite	Does this patient have a urinary tract infection?	Positive LE, positive nitrite, or both	Send urine to laboratory for microscopy, culture and sensitivity and treat if positive	Appropriate use of antibiotics, decreased morbidity
Rule Out				
BNP	Is this breathless patient suffering from heart failure?	56 ng/L	Seek alternative diagnosis	Avoid incorrect diagnosis and treatment with its potential for harm
TnI	Has this patient had a myocardial infarction?	<0.1 μg/L	Consider other possible diagnoses and early discharge	Less worry for patient, reduce unnecessary admissions to cardiac care unit
TSH	Does this patient have hypothyroidism?	2.1 mU/L	No further action	Any patient disquiet allayed
Urine LE and nitrite	Does this patient have a urinary tract infection?	Normal dipstick result	Do not send urine to laboratory, look for alternative cause of symptoms	Inappropriate antibiotic treatment avoided, unnecessary laboratory work avoided
Monitoring				
BNP	Is the patient taking the correct dosage of β-blocker?	No change	Review dosage and patient compliance	No change in symptoms, risk of cardiac event, more clinic visits
BNP	Is the patient taking the correct dosage of β-blocker?	Fallen from 216 to 160 ng/L	No change to dosage, encourage patient	Reduced symptoms and risk of cardiac event
HbA_{1c}	Is patient complying with treatment protocol?	10.6% (no change in a year)	Consider changing treatment, closer monitoring of compliance, clinic visits and consultations with diabetes nurse	Persistently high HbA_{1c} carries increased risk of complications; intervention necessary to decrease risk
HbA_{1c}	Is patient complying with treatment protocol?	5.8%	Congratulate patient, maintain treatment regimen	Continued reduced risk of complications

Continued.

TABLE 13-1 Examples of Clinical Questions in Which a Laboratory Assessment May Be of Value, and the Associated Action and Potential Outcome (Benefit)—*Continued*

Test	Question	Result	Possible Action	Possible Outcome
Prognosis				
BNP	Is this patient's heart failure deteriorating?	Increase from 450 to 650 ng/L in last year	Adjust therapy, perhaps advise on palliative care	Poor prognosis
TnI	What is this patient's risk of a further cardiac event?	0.9 μg/L	Consider intervention	Increased risk without intervention
Her-2/*neu*	What is this patient's prognosis?	3+ by immunohistochemical staining at primary diagnosis	Consider Herceptin treatment	Improvement of poor prognosis by selection of appropriate therapy

around time for blood-gas and electrolyte testing may allow faster discharge from the emergency room,[66] unless other evaluations (such as other laboratory tests or radiological investigations) are rate limiting.[48] Reduced length of stay appeared to be primarily because normal results with the POCTs enabled some patients to be discharged more quickly (i.e., a rule-out decision).[66]

If a result is not received or accessed, it will not contribute to an improved outcome. In a systematic study, Kilpatrick and Holding[50] found when they introduced an electronic transmission of data to the emergency department and admissions unit that a notable number of results were never accessed.

Using the Test Result

In many clinical scenarios, the first criterion for a useful test is that the result leads to a change in the probability of the presence of the target condition. Boyd and Deeks,[11] for example, showed that the (pretest) probability of pulmonary embolism fell from about 0.28 to a posttest probability of 0.041 when the D-dimer test result was less than 500 μg/L. The change in probability does not, in itself, make the decision. The clinician must use this information along with other findings and clinical judgment to make decisions or recommendations about care.

The Clinical Setting of an Outcome Study

The setting of a research study may or may not be the same as that of the individual patient. The evidence from a study may be unreliable when differences exist in age, sex, ethnic origin, lifestyle, prevalence of the disease in the population, or prevalence of comorbidities. Transferability of study results may also be affected by analytical variables, such as patient preparation (effects of fasting, posture, exercise, and biological variation) and method performance (accuracy and precision).

CHARACTERIZATION OF DIAGNOSTIC ACCURACY OF TESTS

When a new test is developed or an old test is applied to a new clinical question, users need information about the extent of agreement of the test's results with the correct diagnoses of patients. For this purpose, researchers design studies in which results from the new test are compared with the results obtained with the reference standard on the same patients. The results of the comparison can be expressed in a number of ways, including sensitivity and specificity, predictive values, likelihood ratios, diagnostic odds ratios, and areas under receiver operating characteristic (ROC) curves (see Chapter 15). We will refer to such studies as diagnostic accuracy studies.

Study Design

In studies of diagnostic accuracy, the results of one test (often referred to as the index test, the test of interest) are compared with those from the reference standard (referred to as the reference test, the best current practice). A "test" can be any method for obtaining additional information on a patient's health status. This includes not only laboratory tests, imaging tests, and function tests but also data from the history and physical examination, and genetic data.

The *reference standard* is the best available method for establishing the presence or absence of the target condition (the suspected condition and/or disease for which the test is to be applied). The reference standard can be a single test, or a combination of methods and techniques, including clinical follow-up of tested patients.

There are several potential threats to the internal and external validity of a study of diagnostic accuracy, of which only the major ones will be addressed in this section. (For more detail and examples, see Chapter 15.) Poor *internal validity* will produce bias, or systematic error, because the

estimates do not correspond to what one would have obtained using optimal methods, whereas poor *external validity* limits the generalizability of the findings, as the results of the study, even if unbiased, do not correspond to settings encountered by the decision maker. For example, the results of a study of patients in a tertiary-care medical center may not be generalizable to patients seen in a general practice, and studies done exclusively in older men may not be applicable to women or children.

The ideal study examines a consecutive series of patients, enrolling all consenting patients suspected of the target condition within a specific period. All of these patients then undergo the index test and then the reference test. The term "consecutive" refers to total absence of any form of selection, beyond the a priori definition of the criteria for inclusion and exclusion, and requires explicit efforts to identify and enroll patients qualifying for inclusion.

Alternative designs are possible. Some studies first select patients known to have the target condition, and then contrast the results of these patients with those from a control group. This approach has been used to characterize the performance of tests in settings in which the condition of interest is uncommon as in maternal serum screening testing for detecting Down syndrome in the fetus. It is also used in preliminary studies to assess the potential of a test before embarking on prospective studies of a series of patients. With this design, the selection of the control group is critical. If the control group consists of healthy individuals only, diagnostic accuracy of the test will tend to be overestimated, as has been shown in an analysis that compared the results of such studies with results of studies of consecutive series of patients.[57] (See Chapter 15 for further discussion.)

In the ideal study, the results of all patients tested with the test under evaluation are contrasted with the results of a single reference standard. If fewer than all patients are verified with the reference standard, then *partial verification* exists, and verification bias may occur if the selection of subjects for reference testing is not purely random. For example, if selection is associated with the outcome of the index test, or the strength of prior suspicion, or both, then verification bias is certain. In a typical case, some patients with negative test results (test-negatives) are not verified by the reference standard if this involves a costly or invasive procedure, and these patients are not included in the analysis. This may result in an underestimation of the number of false-negative results.

A different form of verification bias can happen if more than one reference standard is used, and the two reference standards correspond to different manifestations of disease. This study design can produce *differential verification bias*. Suppose test-positive patients are verified with further testing and test-negative patients are verified by clinical follow-up. An example is the verification of suspected appendicitis, with histopathology of the appendix versus natural history as the two forms of the reference standard. A patient is classified as having a false-positive test result if the additional test does not confirm the presence of disease after a positive index test result. Alternatively, a patient is classified as a false-negative if an event compatible with appendicitis is observed during follow-up after a negative test result. Yet these are different definitions of disease because not all patients who have positive test results by the reference standard would have experienced an event during follow-up if they had been left untreated. The use of two reference standards, one pathological and the other based on clinical prognosis, can affect the assessment of diagnostic accuracy. It can also lead to variability among studies that depend on the proportions of patients verified with each of the two standards. For additional discussion, see Chapter 15.

There is a long-standing debate on whether or not clinical data should be provided to those performing or reading the index test, especially when that test has a subjective component. Withholding this information is known as blinding or masking. Some clinical information is often routinely known by the reader of the test, such as when radiologists see the patients on whom they are performing a test, or a pathologist is told the site from which a biopsy is obtained. To try to withhold such information in the context of a study of diagnostic accuracy may create an artificial scenario that has no counterpart in patient care. Thoughtful attention to this question is important in the early phases of designing a study. For most study questions, masking is preferable, because knowledge of the results will tend to increase agreement of the result of the studied (index) test with the reference standard (test).

The severity of disease in the studied patients with the target condition and the range of other conditions in the other patients (controls) can affect the apparent diagnostic accuracy of a test. For example, if a test that is designed to detect early cancer is evaluated in patients with clinically apparent cancer, the test is likely to perform better than when used for persons who do not yet show signs of the condition. This problem has been called "spectrum bias." Similarly, if a test is developed to distinguish patients with the target condition from patients with a similar condition, it may be misleading to use healthy subjects as controls when evaluating the diagnostic accuracy of the test.

The Reporting of Studies of Diagnostic Accuracy and the Role of the STARD Initiative

Complete and accurate reporting of studies of diagnostic accuracy should allow the reader to detect the potential for bias in the study and to assess the ability to generalize the results and their applicability to an individual patient or group. Reid, Lachs, and Feinstein[77] documented that most studies of diagnostic accuracy published in leading general medical journals either had poor adherence to standards of clinical epidemiological research or failed to provide information about adherence to those standards.[5] A later study showed similar problems in studies of genetic tests. These reports led to efforts at the journal *Clinical Chemistry* in 1997 to produce a checklist for reporting of studies of diag-

nostic accuracy.[12] The quality of reporting in that journal increased after introduction of this checklist,[58] though not to an ideal level.[9]

The work of Lijmer et al[57] showing that poor study design and poor reporting are associated with overestimation of the diagnostic accuracy of evaluated tests indicated the necessity to improve the reporting of studies of diagnostic accuracy for all types of tests, not only those in clinical chemistry. An initiative on Standards for Reporting of Diagnostic Accuracy (STARD) was begun at the 1999 meeting of the Cochrane Diagnostic and Screening Test Methods Working Group. The initiative[7] aimed to improve the quality of reporting of diagnostic accuracy studies by following the model of the successful Consolidated Standards of Reporting Trials (CONSORT) initiative for reporting of trials of therapies (see discussion of outcomes studies later in this chapter).

The key components of the STARD document[7] are a checklist of items to be included in reports of studies of diagnostic accuracy and a flow diagram to document the flow of participants in the study. The checklist was developed from an extensive literature search that identified 75 potential items. The list was pared to 25 items (Figure 13-2) in a consensus meeting of researchers, editors, methodologists, and representatives of professional organizations. The flow diagram (Figure 13-3) has the potential to clearly communicate vital information about the *design* of a study—including the method of recruitment and the order of test execution—and about the *flow* of participants.

The final, single-page checklist (Figure 13-2) has been endorsed by numerous journals (such as *Journal of the American Medical Association [JAMA]* and *Annals of Internal Medicine)* and published in many of them, including all the major journals of clinical chemistry and other leading journals including *Radiology*, *British Medical Journal (BMJ)*, and *Lancet*. A separate document explaining the meaning and rationale of each item and briefly summarizing the available evidence was published in *Annals of Internal Medicine* and *Clinical Chemistry*.[8] The STARD group will prepare updates of the STARD document when new evidence on sources of bias or variability becomes available. In the experience of one of the authors of this chapter (DB), use of the checklist has increased the information content of all manuscripts to which it has been applied at *Clinical Chemistry*, and use of the flow diagram has led to correction of errors in many manuscripts.

Use of the STARD initiative is recommended for all reports of studies of diagnostic accuracy. Most if not all of the content of STARD applies to studies of tests used for prognosis, monitoring, or screening.

OUTCOMES STUDIES

Medical and public health interventions are intended to improve the well-being of patients, the population at large, or population segments. For therapeutic interventions, patients are interested, for example, not only if a drug decreases serum cholesterol or blood pressure (risk factors), but more importantly whether it decreases the risk of heart attack, stroke, and cardiovascular death. Similarly, on the diagnostic side of medicine, patients have little interest in knowing the numerical value of their serum cholesterol concentration or blood pressure unless that knowledge will lead to actions that will in some way improve their quality or quantity of life. For example, a test result may identify the need for a life-saving therapeutic intervention for an existing disease or it may lead to a change in lifestyle that will decrease risk of developing a disease. At other times, the test result itself can provide valuable reassurance, as when a genetic test indicates that a family member does not carry a mutation that is present in the family. In still other cases, a laboratory test may provide prognostic information that allows the patient to better plan for the future despite a bad prognosis, or it may provide reassurance that symptoms are not signs of serious disease, thus allowing him or her to better manage the symptoms without fear. The test-related outcomes in these examples range from preventing imminent death to being better able to plan for death.

WHAT ARE OUTCOMES STUDIES?

Outcomes may be defined as results of medical interventions in terms of health or cost. "Patient outcomes" are results that are perceptible to the patient.[3] Outcomes that have been studied commonly include mortality, complication rates (such as the nosocomial infection rate), length of stay in the hospital, waiting times in a clinic, cost of care, and patients' satisfaction with care. In studying and comparing diagnostic tests, other highly desirable "outcomes" are an improved ability to make a correct diagnosis of a treatable condition and an improved ability to exclude a diagnosis or monitor treatment or screen for disease. Test results themselves are not widely considered to be outcomes, but an argument can be made that they should be considered as such when it is certain that real outcomes will change for the better with a superior test. Some tests are increasingly being used as surrogate outcome markers in intervention studies when a strong relationship has been documented between the test result and morbidity or mortality; examples include the use of HbA_{1c} and the urine albumin : creatinine ratio in studies on the management of diabetes mellitus.

Outcomes studies must be distinguished from studies of prognosis. Studies of the prognostic value of a test ask the question, "Can the test be used to predict an outcome?" By contrast, outcomes studies ask questions such as, "Does use of the test improve outcomes?" For example, a study of the former type asks the question, "Does the concentration of a cardiac troponin in serum correlate with the mortality rate after myocardial infarction?" An outcomes study might ask, "Is the mortality rate of patients with suspected myocardial infarction decreased when physicians use troponin testing to guide therapy?" Recent outcomes studies have asked questions such as the following: "Is availability of POCT in the emergency room, compared with testing

Section and Topic	Item #		On page #
TITLE/ABSTRACT/ KEYWORDS	1	Identify the article as a study of diagnostic accuracy (recommend MeSH heading sensitivity and specificity).	
INTRODUCTION	2	State the research questions or study aims, such as estimating diagnostic accuracy or comparing accuracy between tests or across participant groups.	
METHODS		Describe	
Participants	3	The study population: The inclusion and exclusion criteria, setting and locations where the data were collected.	
	4	Participant recruitment: Was recruitment based on presenting symptoms, results from previous tests, or the fact that the participants had received the index tests or the reference standard?	
	5	Participant sampling: Was the study population a consecutive series of participants defined by the selection criteria in items 3 and 4? If not, specify how participants were further selected.	
	6	Data collection: Was data collection planned before the index test and reference standard were performed (prospective study) or after (retrospective study)?	
Test methods	7	The reference standard and its rationale.	
	8	Technical specifications of material and methods involved including how and when measurements were taken, and/or cite references for index tests and reference standard.	
	9	Definition of and rationale for the units, cutoffs and/or categories of the results of the index tests and the reference standard.	
	10	The number, training, and expertise of the persons executing and reading the index tests and the reference standard.	
	11	Whether or not the readers of the index tests and reference standard were blind (masked) to the results of the other test and describe any other clinical information available to the readers.	
Statistical metheds	12	Methods for calculating or comparing measures of diagnostic accuracy, and the statistical methods used to quantify uncertainty (e.g. 95% confidence intervals).	
	13	Methods for calculating test reproducibility, if done.	
RESULTS		Report	
Participants	14	When study was done, including beginning and ending dates of recruitment.	
	15	Clinical and demographic characteristics of the study population (e.g. age, sex, spectrum of presenting symptoms, comorbidity, current treatments, recruitment centers).	
	16	The number of participants satisfying the criteria for inclusion that did or did not undergo the index tests and/or the reference standard; describe why participants failed to receive either test (a flow diagram is strongly recommended).	
Test results	17	Time interval from the index tests to the reference standard, and any treatment adminstered between.	
	18	Distribution of severity of disease (define criteria) in those with the target condition; other diagnoses in participants without the target condition.	
	19	A cross tabulation of the results of the index tests (including indeterminate and missing results) by the results of the reference sandard; for continuous results, the distribution of the test results by the results of the reference standard.	
	20	Any adverse events from performing the index tests or the reference standard.	
Estimates	21	Estimates of diagnostic accuracy and measures of statistical uncertainly (e.g. 95% confidence intervals).	
	22	How indeterminate results, missing responses, and outliers of the index tests were handled.	
	23	Estimates of variability of diagnostic accuracy between subgroups of participants, readers, or centers, if done.	
	24	Estimates of test reproducibility, if done.	
DISCUSSION	25	Discuss the clinical applicability of the study findings.

performed in the hospital laboratory, associated with a decreased length of stay for patients in the emergency department?"[48,66,73] and "Does routine testing of elderly patients before cataract surgery decrease postoperative complication rates?"[84]

Many test attributes are amenable to studies of outcomes. Studies can address not only the test availability or non-availability but also such attributes as the methodology used for a measurement, the analytical quality of test performance (e.g., precision), the turnaround time (as for POCT in the emergency department), and the method of reporting of test results (e.g., with or without extensive interpretation of the result).

Why Outcomes Studies?

Outcomes studies have taken on considerable importance in medicine. On the therapeutic side of medicine, few drugs can be approved by modern government agencies (or paid for by healthcare organizations or health insurers) without randomized, controlled trials of their safety and effectiveness. Increasingly, diagnostic testing is entering a similar environment in which physicians, governments, commercial health insurers, and patients demand evidence of effectiveness of diagnostic procedures. To appreciate this, one need only recall the enormous interest in controversies about the value of mammography and the effectiveness of measuring prostate-specific antigen in serum. These issues (and many others) hinge on demonstration of improved outcomes.

In the United States, the important Joint Commission on Accreditation of Healthcare Organizations (JCAHO) defines *quality* as increased probability of desired **outcomes** and decreased probability of undesired **outcomes.** If a healthcare organization, or a unit of it, such as the clinical laboratory,

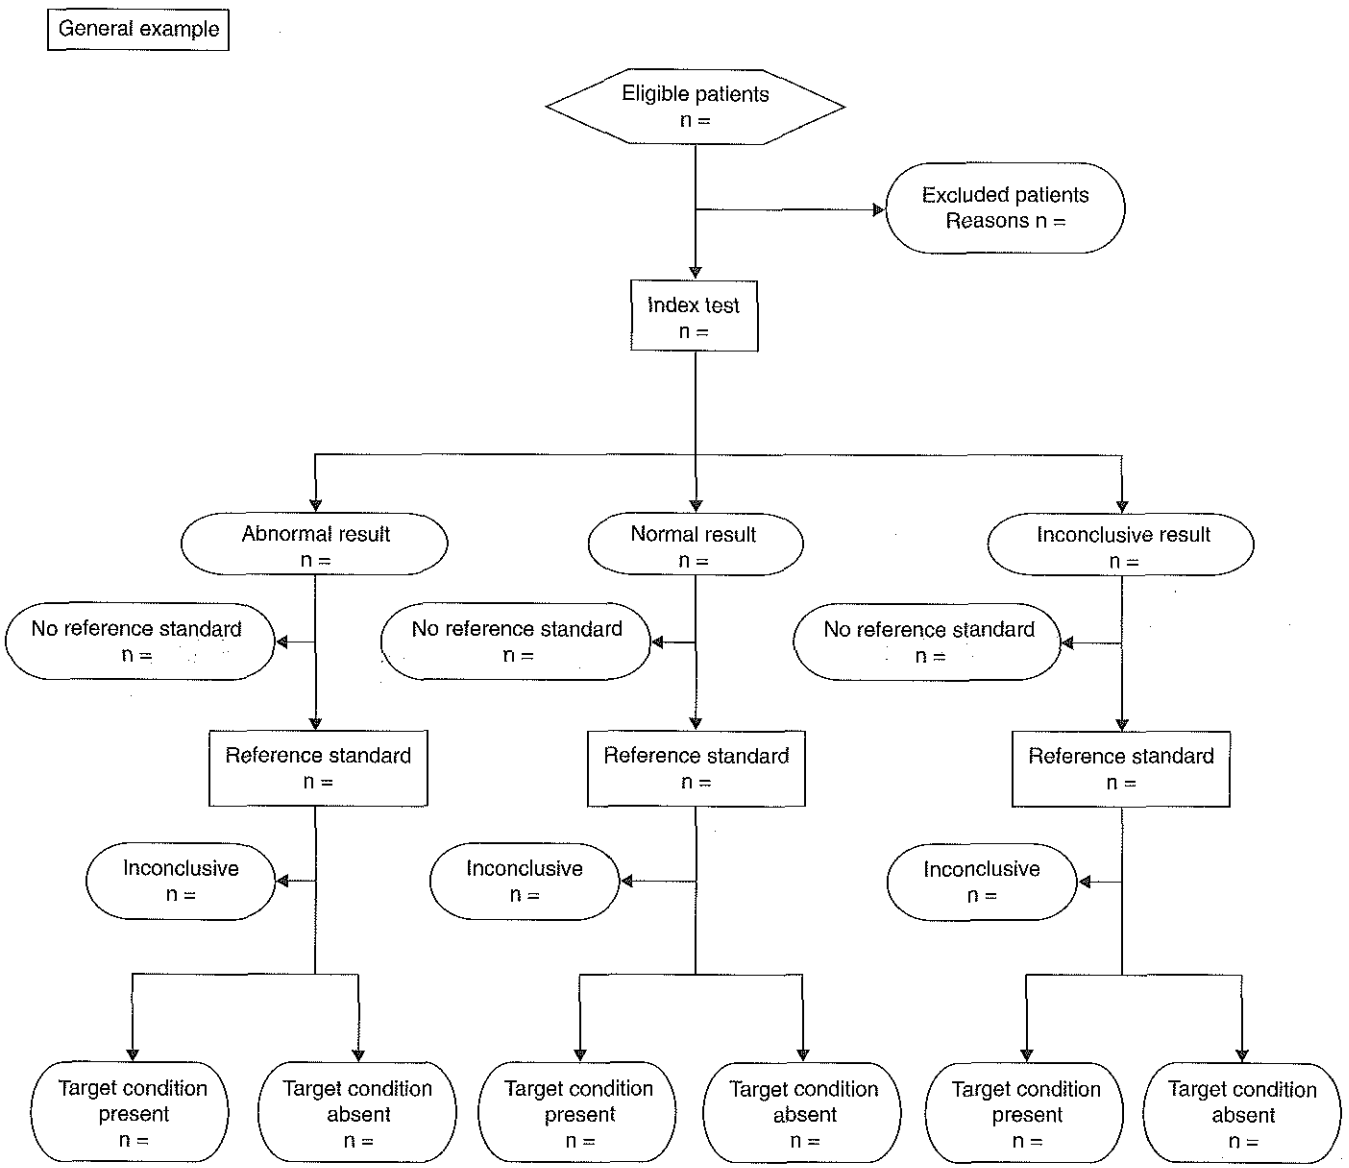

Figure 13-3 STARD flow diagram.

wishes to propose that its quality is high or that it contributes to the quality of the institution, the message is clear.

Design of Studies of Medical Outcomes

The randomized controlled trial (RCT) is the de facto standard for studies of the health effects of medical interventions. In these studies, patients are randomized to receive either a therapy to be tested or an alternative (either a placebo or a conventional treatment), and an outcome is measured. RCTs have been used to evaluate therapeutic interventions, including drugs, radiation therapy, and surgical interventions, among others. The measured outcomes vary from hard evidence, such as mortality and morbidity, to softer evidence, such as patient-reported satisfaction and surrogate end points typified by markers of disease activity (e.g. HbA_{1c} and urine albumin : creatinine ratio as mentioned earlier).

The high impact of RCTs of therapeutic interventions led to scrutiny of their conduct and reporting. An interdisciplinary group (largely clinical epidemiologists and editors of medical journals) developed a guideline known as CONSORT[61] for the conduct of these studies. Although initially designed for trials of therapies, CONSORT provides useful reminders when designing or appraising outcomes studies of tests in clinical chemistry and molecular diagnostics. The key features of the guideline are a checklist (Figure 13-4) of items to include in the report and a flow diagram (Figure 13-5) of patients in the study.

The optimal design of an RCT of a diagnostic test is not always obvious. A classical design is to randomize patients to

Checklist of items to include when reporting a randomized trial

PAPER SECTION And topic	Item	Description	Reported on page #
TITLE & ABSTRACT	1	How participants were allocated to interventions (*e.g.*, "random allocation," "randomized," or "randomly assigned").	
INTRODUCTION Background	2	Scientific background and explanation of rationale.	
METHODS Participants	3	Eligibility criteria for participants and the settings and locations where the data were collected.	
Interventions	4	Precise details of the interventions intended for each group and how and when they were actually administered.	
Objectives	5	Specific objectives and hypotheses.	
Outcomes	6	Clearly defined primary and secondary outcome measures and, when applicable, any methods used to enhance the quality of measurements (*e.g.*, multiple observations, training of assessors).	
Sample size	7	How sample size was determined and, when applicable, explanation of any interim analyses and stopping rules.	
Randomization -- Sequence generation	8	Method used to generate the random allocation sequence, including details of any restriction (*e.g.*, blocking, stratification).	
Randomization -- Allocation concealment	9	Method used to implement the random allocation sequence (*e.g.*, numbered containers of central telephone), clarifying whether the sequence was concealed until interventions were assigned.	
Randomization -- Implementation	10	Who generated the allocation sequence, who enrolled participants, and who assigned participants to their groups.	
Blinding (masking)	11	Whether or not participants, those administering the interventions, and those assessing the outcomes were blinded to group assignment. When relevant, how the success of blinding was evaluated.	

Figure 13-4 CONSORT checklist. *Continued.*

Statistical methods	12	Statistical methods used to compare groups for primary outcome(s); methods for additional analyses, such as subgroup analyses and adjusted analyses.	
RESULTS Participant flow	13	Flow of participants through each stage (a diagram is strongly recommended). Specifically, for each group report the numbers of participants randomly assigned, receiving intended treatment, completing the study protocol, and analyzed for the primary outcome. Describe protocol deviations from study as planned, together with reasons.	
Recruitment	14	Dates defining the periods of recruitment and follow-up.	
Baseline data	15	Baseline demographic and clinical characteristics of each group.	
Numbers analyzed	15	Number of participants (denominator) in each group included in each analysis and whether the analysis was by "intention-to-treat." State the results in absolute numbers when feasible (*e.g.*, 10/20, not 50%).	
Outcomes and estimation	17	For each primary and secondary outcome, a summary of results for each group, and the estimated effect size and its precision (*e.g.*, 95% confidence interval).	
Ancillary analyses	18	Address multiplicity by reporting any other analyses performed, including subgroup analyses and adjusted analyses, indicating those pre-specified and those exploratory.	
Adverse events	19	All important adverse events or side effects in each intervention group.	
DISCUSSION Interpretation	20	Interpretation of the results, taking into account study hypotheses, sources of potential bias or imprecision, and the dangers associated with multiplicity of analyses and outcomes.	
Generalizability	21	Generalizability (external validity) of the trial findings.	
Overall evidence	22	General interpretation of the results in the context of current evidence.	

Figure 13-4 *Cont'd*

receive or not receive a test, and then to modify therapy from conventional therapy to a different therapy based on the test result in the tested patients. This approach leads to interpretive problems.[6] For example, if the new therapy is always effective, the tested group will always fare better even if the test is a coin toss, because only the tested group had access to the new therapy. The conclusion that the testing was valuable would thus be wrong. A similar problem occurs if the tested group had merely an increased access to the therapy. (A possible example is the apparent benefit of fecal occult blood testing in decreasing the incidence of colon cancer where the tested group is more likely to undergo colonoscopy and removal of premalignant lesions in the colon. A random selection of patients for colonoscopy might achieve results similar to the results for the group tested for fecal occult blood.) This problem will lead to the erroneous conclusion that the test itself is useful. By contrast, if the new therapy is always worse than the conventional treatment, patients in the tested group will do worse and the test will be judged worse than useless, no matter how accurate it is. Similarly, if the two treatments are equally effective, the outcomes will be the same with or without testing; this scenario will lead to the conclusion that the test is not good, no matter how diagnostically accurate it is. When a truly better therapy becomes available, the test may prove to be valuable, so it is important to not discount the test's potential based on a study with a new therapy that offers no advantage over the old therapy.

Bossuyt and colleagues[6] describe a study design to determine whether ultrasound testing of the fetus can be used to

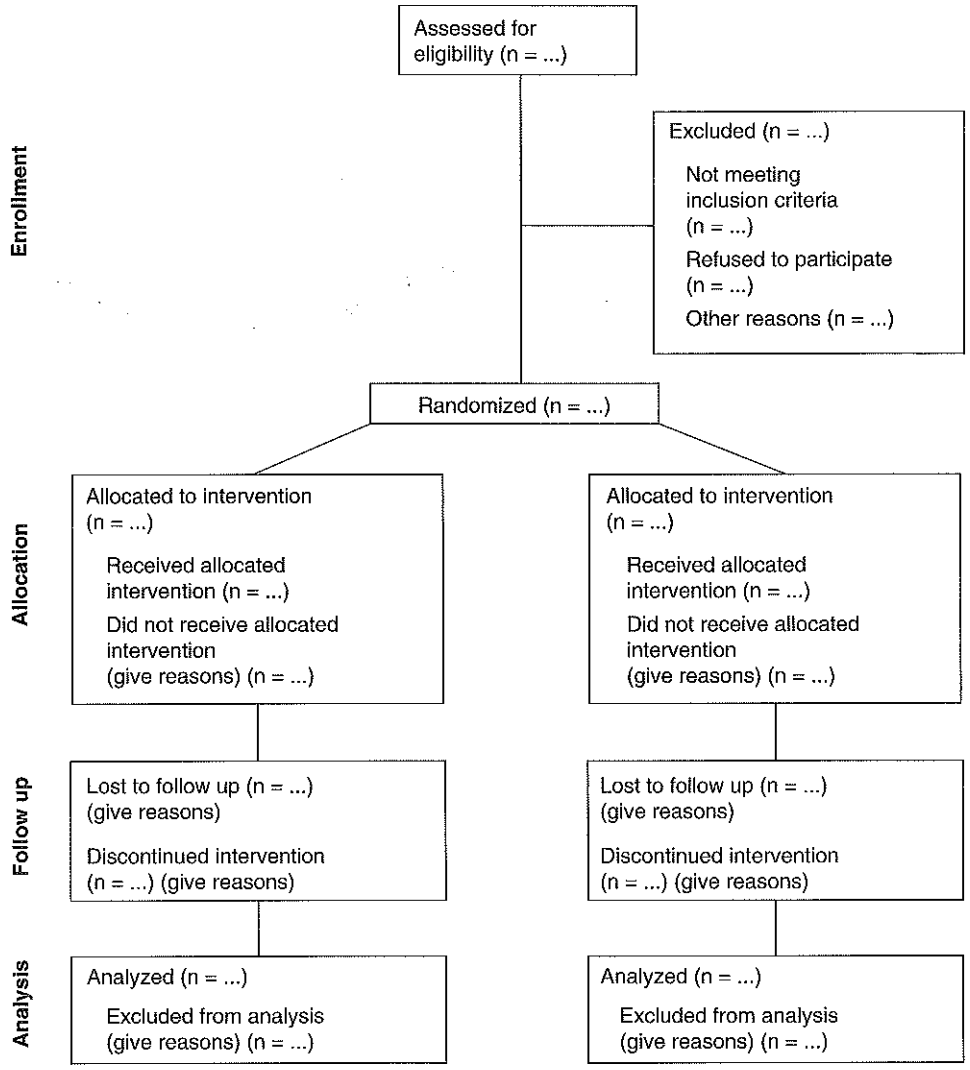

Figure 13-5 CONSORT flow diagram for patients in an RCT.

identify those women with growth-restricted fetuses who can be safely managed at home rather than in the hospital. In a common study design, women with fetuses showing intrauterine growth restriction (IUGR) are randomized to receive Doppler ultrasound. Women with positive test results would be kept in the hospital and those with negative test results would go home. Women in the control arm would stay in the hospital, the usual approach. One can see here that if some women benefit from home care, whereas all other women do equally well with either of the two treatments, home care patients will do better regardless of the intrinsic value of the ultrasound test. Thus patients in the tested arm will fare better, and the testing itself will erroneously be declared a success. By contrast, a proper interpretation would be that the strategy worked well, and a testable hypothesis might be generated from the study that all patients can be sent home without testing.

Alternative designs have been described to address the question of use of ultrasound in women with IUGR.[6] In one design, all patients undergo the new test, but the results are hidden during the trial. Patients are randomized to receive or not receive the new therapy. In this design, the new test should be adopted only if there is an improvement in patient outcome caused by switching to the new therapy, and if that improvement in outcome is associated with the test outcome. For example, the improvement may be larger in the subgroup that had positive test results on ultrasound compared with the subgroup that had negative test results.

An RCT is not always feasible. Alternatives to the RCT include studies that use historical or contemporaneous control patients in whom the intervention was not undertaken. Other studies include patients with and patients without the outcome of interest. These studies are called case-control studies. Uncertainty about the comparability of the controls and the patients in such designs is a threat to the validity of these studies.

Researchers have turned to other methods for exploring the outcomes of testing strategies. To address the multitude of available options when several tests are available, decision analysis has been proposed. These studies rely on a model

that links data on diagnostic accuracy with data on health outcomes. Patients with true-positive test results receive the benefits of treatment for the target condition, in contrast with patients who have true-negative test results. On the other hand, those with false-positive test results undergo the risk of the side effects associated with treatment, without the benefits. For an example, see Perrier et al.[74]

SYSTEMATIC REVIEWS OF DIAGNOSTIC TESTS

Systematic reviews are recent additions to the medical literature. In contrast to traditional "narrative" reviews, these reviews aim to answer a precisely defined clinical question and to do so in a way that is transparent and designed to minimize bias. Some of the defining features of systematic reviews are (1) a clear definition of the clinical question to be addressed, (2) an extensive and explicit strategy to find all studies (published or unpublished) that may be eligible for inclusion in the review, (3) criteria by which studies are included and excluded, (4) a mechanism to assess the quality of each study and, in some cases, (5) synthesis of results by use of statistical techniques of meta-analysis. By contrast, traditional reviews are subjective, are rarely well focused on a clinical question, lack explicit criteria for selection of studies to be reviewed, do not indicate criteria to assess the quality of included studies, and rarely can use meta-analysis.

The explicit methodology of systematic reviews suggests that persons skilled in the art of systematic reviewing should be able to reproduce the data of a systematic review, just as researchers in chemistry or biochemistry expect to be able to reproduce published primary studies in their fields. This concept strengthens the credibility of systematic reviews, and workers in the field of EBM generally consider well-conducted systematic reviews of high-quality primary studies to constitute the highest level of evidence on a medical question.

WHY SYSTEMATIC REVIEWS?

The explosion of research and the vastness of the medical literature are such that no one can read, much less digest, all relevant work. The massive amount of new technology, the poor quality of narrative reviews,[65] and the necessity to provide an accurate digest for practicing clinicians[36] constitute the background to the call for a more systematic review of literature.

Systematic reviews can achieve multiple objectives.[44] They can identify the number, scope, and quality of primary studies by using an extensive search strategy; provide a summary of the diagnostic accuracy of a test; compare the diagnostic accuracies of tests; determine the dependence of reported diagnostic accuracies on quality of study design; identify dependence of diagnostic accuracy on characteristics of the patients or method for the test; and identify areas that require further research and recognize questions that are well answered and for which further studies may not be necessary.

CONDUCTING A SYSTEMATIC REVIEW

Systematic reviewing is time consuming and requires multiple skills. Usually a team is required, and the team should include at least one person experienced in the science and art. The team must agree on the clinical problem to be tackled and on the scope of the review.

An early step in preparation for performing a systematic review is to identify whether a similar review has been undertaken recently. Among other things, such a search will help to focus the review. The Cochrane Collaboration provides an excellent resource of reviews, but unfortunately few are reviews of diagnostic tests.[95] The Database of Abstracts of Reviews of Effectiveness (DARE),[69] which is run by the Centre for Reviews and Dissemination at the University of York in the United Kingdom, contains reviews of some diagnostic tests. A third resource is the Bayes Library of Diagnostic Studies and Reviews, which is associated with the Cochrane Collaboration[42] (http://www.bice.ch/engl/content_e/bayes_library.htm, accessed March 18, 2004). Other resources include electronic databases, such as PubMed and Embase, and recent clinical practice guidelines, which are likely to cite systematic reviews that were available at the time of the guideline's development (see section on guidelines later in this chapter). Horvath et al[43] list additional sources.

The review team must develop a protocol for the project. A protocol should include,[2,43,49] in addition to a title, background information, composition of the review group, and a timetable:

- The clinical question(s) to be addressed in the review
- Search strategy
- Inclusion and exclusion criteria for selection of studies
- Methodology of and checklists for critical appraisal of studies
- Methodology of data extraction and data extraction forms
- Methodology of study synthesis and summary measures to be used

Description of all of the details is beyond the scope of this chapter and only some highlights will be discussed. Review of the references cited here is recommended before embarking on a systematic review.

The Clinical Question and Criteria for Selection of Studies

Among the steps in conducting a systematic review of a diagnostic test (Box 13-1), the most important is the identification of the clinical question for which the test result is required to give an answer, and thus formulation of the question that forms the basis of the review. Two types of questions can be addressed in a systematic review in diagnostic medicine: one type is related to the diagnostic accuracy of a test, and the other to the clinical value (to patients or to others) of using the test. The questions that arise are similar in structure but require different approaches.

BOX 13-1 Selected Key Steps in a Systematic Review of a Diagnostic Test

Identify the clinical question
Define the inclusion and exclusion criteria
Search the literature
Identify the relevant studies
Select studies against explicit quality criteria
Extract data and assess quality
Analyze and interpret data
Present and summarize findings

Examples:

Type 1 question regarding diagnostic accuracy of a test:

> In patients coming to the emergency department with shortness of breath, how well does B-type natriuretic peptide (BNP) or N-terminal pro-BNP predict (identify the presence of) heart failure as assessed by the cardiac ejection fraction measured by echocardiography?

Type 2 question regarding the value of a test in improving patient outcomes (called a phase 4 evaluation of a test by Sackett and Haynes[80]):

> In patients admitted to the hospital for treatment of heart failure, how well does use of BNP or N-terminal pro-BNP help as a guide to therapy, improve the ability to treat heart failure as assessed by the rate of subsequent readmission for heart failure?

Note that each question (1) identifies the patient's problem (shortness of breath and the clinical setting [emergency department or hospital]), (2) the test being used (BNP or N-terminal pro-BNP), (3) the reference standard for the diagnosis (ejection fraction as measured by echo) or for the clinical outcome (rate of subsequent readmission), and (4) an outcome (ability to detect the presence of heart failure or ability to treat heart failure).

More complex questions often arise. For example, a type 1 question may involve comparing the diagnostic accuracies of two or more tests, or it may address the improvement in diagnostic accuracy from adding results of a new test to results of an existing test or tests. A complex type 2 question may involve the utility of therapeutic drug testing at the time of a clinic visit to reduce clinic visits by helping to establish optimum drug dosages. In all cases, however, it is usually best that the clinical question be specific and focused on defined clinical scenarios and clinical settings.

The clinical question leads to inclusion and exclusion criteria for studies to be included in the review. These criteria include the patient cohort and setting in which the test is to be used, as well as the outcome measures to be considered. These are all important as both the "patient setting" and the nature of the question affect the diagnostic performance of a test.[75]

Until recently, methodologists interested in systematic reviews have focused on studies of the effects of interventions, especially drugs, on patient outcomes. That work is generally applicable to systematic reviews of diagnostic tests that start with a question of the second type above. The opportunities to use the techniques, however, are limited as it is unusual to find more than one study on any combination of a test and an outcome. We therefore focus on systematic reviews of the diagnostic accuracy of tests and express the hope that the quality of primary studies will continue to improve so that many such systematic reviews will become feasible.

When the questions to be addressed are defined, the review group must agree on the scope of the review. Irwig et al[44] summarized the two main approaches to defining the scope of a systematic review of studies of diagnostic accuracy:

- Restrict the review to studies of high quality directly applicable to the problem of immediate interest to the reviewer.
- Explore the effect of variability in study quality and other characteristics (setting, type of population, disease spectrum, etc.) on estimates of accuracy, using subgroup analysis or modeling.

The second approach is more complex, but allows estimates of such things as the applicability of estimates of diagnostic accuracy to different settings and the effect of study design and inherent patient characteristics (e.g., age, sex, symptoms) on estimates of a test's diagnostic accuracy.

Search Strategy

Searching of the primary literature is usually carried out in three ways: (1) an electronic search of literature databases, (2) hand searching of key journals, and (3) review of the references of key review articles. It is usual to search both Medline and Embase, as the overlap between the two can be as low as 35%.[90] Searching of databases is a detailed exercise and the help of a librarian or information scientist is recommended. An incorrectly structured search can generate a large number of irrelevant references and miss crucial references.[53] Guidance that is tailored to searching for studies of diagnostic accuracy in the published literature is available in Irwig et al.[44]

Additional studies may be found in the "gray" literature that is not indexed by the major databases. These sources include theses, conference proceedings, technical reports, and monographs. Consultation with individuals active in the field may uncover studies in these sources and studies that are being prepared for publication.

Data Extraction and Critical Appraisal of Studies

Identified papers should be read independently by two persons and data extracted according to a template. A checklist of items to extract from primary studies in preparing a

systematic review on test accuracy is available online[44] and on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/. The STARD checklist[7] can also be used as an additional guide in designing the template.

The quality of studies must be assessed as part of the systematic review. Rating schemes for the quality of primary studies have been concerned mostly with studies of therapeutic interventions. These schemes have focused on the type of study design, with large RCTs routinely considered to have the highest level of quality and other designs given lower ratings. Glasziou et al[37] have pointed out, however, that different types of clinical questions (such as questions related to diagnostic approaches) often require different types of study design. Thus, a randomized trial, though ideal for studies of the effects of interventions, is not the most appropriate design to study whether (their examples) computerized or human reading of cervical smears is better (or to study the natural history of a disease or the cause of a disease, etc.). Moreover, a study may use a good design but suffer from serious drawbacks in other dimensions, such as the number of patients lost to follow-up. Thus adequate grading of the quality of studies must go beyond the categorization of study design.[37]

Summarizing the Data

The characteristics and data from critically appraised studies should be presented in tables. The data should include sensitivities, specificities, and likelihood ratios wherever possible. These can then be summarized in plots that provide an indication of the variation among studies. The summary should also include an assessment of the quality of each study, using an explicit scoring system. A review should also present critical analysis of the data highlighted in the review.

Meta-analysis

It may be possible to undertake a meta-analysis if data are available from a number of similar studies (i.e., asking the same question in the same type of patients and in the same or similar clinical settings). Meta-analyses can explore sources of variability in the results of clinical studies, increase confidence in the data and conclusions, and signal when no further studies are necessary. For guidelines on conduct of meta-analyses of RCTs, see the Quality of Reporting of Meta-analyses (QUOROM) statement at http://www.consort-statement.org/QUOROM.pdf (accessed April 22, 2004).

Although meta-analyses are hampered in diagnostic research by the paucity of high-quality primary studies,[44] the quality of these studies is improving.[58] For descriptions of meta-analytic techniques in diagnostic research, including the summary ROC curve, see papers by Irwig et al[45,46] and Deeks[19] and the book chapter by Boyd and Deeks.[11] Deeks has argued that likelihood ratios provide the most transparent expression of the utility of a test, because they enable the clinician to calculate the posttest probability if the pretest probability is known.[19]

ECONOMIC EVALUATIONS OF DIAGNOSTIC TESTING

Healthcare costs worldwide have surged in recent decades. For example, the United States spent $1.55 trillion dollars on healthcare in 2002, or 14.9% of its gross domestic product (see http://www.cms.hhs.gov/statistics/nhe/historical/t1.asp, accessed March 18, 2004). Although the direct laboratory costs are small in comparison, the tests have a profound influence on medical decisions and therefore total costs.

A Hierarchy of Evidence

A hierarchy of evidence regarding clinical tests[34] begins with assessment of the test's technical performance and proceeds through the study of the test's diagnostic performance to an identification of potential benefits and thus to economic evaluation. The hierarchy has also been expressed as moving up from the efficacy of a test through efficiency to the effectiveness of a test.[60] This hierarchy of evidence can also be seen in the context of the data that are required to make decisions about the implementation of a test.[76] It therefore lies at the heart of the process of policy making and service management.[64] Economic evaluation provides a means of evaluating the comparative costs of alternative care strategies and providing a means of evaluating health outcomes at the highest level in terms of life years gained and social benefit.[26,89]

Methodologies for Economic Evaluations

Health economics is concerned with the *cost* and *consequences* of decisions made about the care of patients. It therefore involves the identification, measurement, and valuation of both the costs and the consequences. The process is complex and is an "inexact science."[67] The approaches to economic evaluation include (1) cost minimization, (2) cost benefit, (3) cost effectiveness, and (4) cost utility analysis (Table 13-2).

Cost minimization can be considered as the simplest approach and provides the least information; it is an evaluation of the costs of alternative approaches that produce the same outcome. In the area of diagnostic testing, it is applicable only to the cost of alternative suppliers of the same test, device, or instrument. It is therefore a technique that is limited to the procurement process where the specifications of the service are already established and the outcomes clearly defined. It might be considered as providing the "cost per test," an often quoted parameter that is not, however, a true economic evaluation because it does not identify an outcome except the provision of a test result.

Cost-benefit analysis determines whether the cost of the benefit exceeds the cost of the intervention and therefore whether the intervention is worthwhile. The value of the consequence or benefit is assessed in monetary terms; this

TABLE 13-2 Approaches to Economic Evaluations

Type of Evaluation	Test Evaluated	Effect or Outcome	Decision Criteria
Cost minimization	Alternative tests or delivery options	Identical outcomes	Least expensive alternative
Cost benefit	Alternative tests or delivery options	Improved effect or outcome	Effect evaluated purely in monetary terms
Cost effectiveness	Alternative tests or delivery options	Common unit of effect but differential effect	Cost per unit of effect (e.g., dollars per life years gained)
Cost utility	Alternative tests or delivery options	Improved effect or outcome	Outcome expressed in terms of survival and quality of life

can be quite challenging, because it may require the analyst to equate a year of life to a monetary amount. There are a number of methods, including the "human capital approach," which assesses the individual's productivity (in terms of earnings), and the "willingness to pay approach," which is more of a modeling approach having determined by questionnaire what individuals are prepared to pay. Cost-benefit evaluation is not widely used, but it might have some value in comparisons of different testing modalities.

Cost-effectiveness analysis looks at the most efficient way of spending a fixed budget and the effects are measured in terms of a natural unit. The ultimate natural unit is the life year, but more practical measures include reduction in the frequency of hypoglycemic episodes, or number of strokes prevented. Surrogate measures with clear relationships to morbidity and mortality have also been used (e.g., change in blood pressure). When assessing an intervention, the number of cases of disease prevented may be used as a measure of benefit, as in the case of alternative approaches to the management of patients with suspected peptic ulcer.[30] In this study, investigative and treatment strategies were compared for outcome measures of costs per ulcer cured and cost per patient treated. The serological testing strategy was found to be more effective than endoscopy by both measures.

Cost-utility analysis includes the quality and the quantity of the health outcome, or in other words looking at the quality of the life years gained. The cost of the intervention is assessed in monetary terms, but the outcomes are expressed in "quality-adjusted life years" (QALYs). Approaches that assess the quality of life include Quality of Wellbeing,[47] Heath Utilities Index,[94] and EuroQol.[51] Cost-utility analysis has seen little use in the study of diagnostic tests probably because of the complexity of the clinical process involving both diagnostic test and treatment necessary to produce a measurable clinical outcome. It has, however, been used to assess the utility of some screening programs.

The inclusion of a quality of life component can affect choices among alternatives. In the Centers for Disease Control and Prevention Diabetes Cost-Effectiveness Study, the lifetime costs and benefits of opportunistic screening for diabetes were compared with those of current practice,[15] with primary outcome measures of life years saved and QALYs. The incremental cost effectiveness was found to be $35,768 per life year gained and $13,376 per QALY, showing that adjustment for quality of life has a major impact on the cost effectiveness. This suggests that in addition to the extension of life through screening there is also a gain in the quality of life that increases the attractiveness of the benefits accruing from screening.

The addition of new technology often increases both cost and benefit. A cost-effectiveness study[33] of screening for colorectal cancer (versus no screening) showed that the "least expensive" strategy was a single sigmoidoscopy at 55 years of age, with an incremental cost-effectiveness ratio of $1200 per life year saved. Alternative strategies gave incremental cost-effectiveness ratios of $21,200, $51,200, and $92,900 with the addition of increasingly complex and frequent screening for fecal occult blood.

When tests increase both the cost and benefit, decisions about their use will depend on factors such as willingness to pay and other political and individual pressures. A figure of $50,000 per QALY has been used in the United States as a reference point, the figure deriving from a decision by the U.S. Congress to approve dialysis treatment for end-stage renal failure.[54] Although providing useful comparative data, there are concerns about the use of tables of cost per QALY.[23]

The underlying issue of economic evaluations is to compare the costs that will be incurred with an estimate of the gain, and for this there are four possible findings and three possible decisions:

- Test more costly but providing greater benefit—possibly introduce depending on overall gain
- Test more costly but providing less benefit—do not introduce test
- Test less costly but providing greater benefit—introduce test
- Test less costly but providing less benefit—possibly introduce test depending on the size of the loss in the benefit and the magnitude of savings (which may be able to produce a demonstrably greater benefit if spent on a different intervention or test).

These options have been expressed graphically in a two-dimensional plot called the "cost- effectiveness plane"[4,70] with cost on one axis and benefit on the perpendicular axis.

Quality of Economic Evaluations

In exactly the same way as for studies on diagnostic performance and for outcomes studies, there is a minimal set of criteria for evaluating an economic study of a diagnostic test. A suggested list of criteria includes[22]:

- Clear definition of economic question including perspective of the evaluation (e.g., perspective of a patient or society or an employer or a health insurance company or a hospital administrator; long-term versus short-term perspective)
- Description of competing alternatives
- Evidence of effectiveness of intervention
- Clear identification and quantification of costs and consequences including incremental analysis
- Appropriate consideration of effects of differential timing of costs and benefits
- Performance of sensitivity analysis (How sensitive are results to changes in assumptions or in input, e.g., cost of drugs or expected benefit in life years?)
- Inclusion of summary measure of efficiency, ensuring that all issues are addressed

Two reviews of economic evaluations of diagnostic tests have shown poor adherence to the criteria outlined above, with only about half of the evaluated papers meeting the criteria.[21,85]

Perspectives of Economic Evaluations

The perspective from which an economic evaluation is performed affects the design, conduct, and results of the evaluation. The perspective may, for example, be that of a patient, a payer (government health agency or health insurance company), or society. The perspective may be long term or short term. The perspective is a practical consideration when attempting to assess the benefit of a particular test or device as part of a more complex clinical protocol. Perspective is also important in relation to many of the routine decisions made about a diagnostic test. The questions below illustrate the importance of perspective:

- What is the cost of the test result produced on analyzer A compared with analyzer B?
- What is the cost of the test result produced by laboratory A compared with laboratory B?
- What is the cost of the test result produced by POCT compared with the laboratory?
- Will provision of rapid testing for the emergency department reduce the length of patients' stays in the department and thus decrease cost for the hospital?
- Will HbA_{1c} testing in a clinic save time for *patients* by providing results at the time of the clinic visit? Will it save money for the patients' *employers* by reducing employees' time away from work for physician appointments? Will it save time for the physician and thus money for the *clinic*? Will it improve care of diabetes (perhaps by facilitating counseling at the time of the clinic visit) for the *patient* as indicated by independent measures of glycemic control? Will it save money for the *health system* by improving glycemic control and thus decreasing hospitalizations? Will it provide benefit for *society* by decreasing society's healthcare costs (for hospitalizations) and increasing patients' functioning and contributions to society?

The first scenario is the type of evaluation made when making a deal, and is a simple procurement exercise. The outcome is the same—the provision of a given test result, to a given standard of accuracy and precision within a given time (the specification). The second question might appear to be the same, but it is not and will undoubtedly have to take into account other issues, namely the logistical issues associated with sample transport or the level of communication support provided by the laboratories. To make a relevant evaluation concerning the value of POCT, it is important to also take into account the implications outside of the laboratory that may result from the delay in sending the sample to another laboratory.

Most economic evaluations of diagnostic tests will have a perspective beyond the bounds of the laboratory if the value of the test is to be appreciated and understood. Unfortunately, many of the early economic data on POCT looked solely at the costs of producing the test result.[56] The studies overlooked the potential value of the key objective of producing the result more quickly so that a decision can be made immediately and a treatment instituted or changed. When a test is proposed to reduce the use of other resources within the hospital (e.g., use of drugs or blood products or other expensive diagnostic technology) the expectation is that the clinical outcome will be unchanged (e.g., the patient is not put at risk by using less blood or the less expensive technology). When provision of a test result may have a longer-term impact, as in management of chronic disease, use of intermediate measures of outcome may be especially important.

Choice of Outcome Measures

Tests are not always evaluated in terms of life years gained. Even for cost-effectiveness and cost-utility studies, surrogate clinical markers and surrogate economic markers may have a place.[91] The use of surrogate markers of clinical outcome requires the existence of a clear, demonstrated relationship between the marker and morbidity and mortality. Even if such a relationship is demonstrated, however, changes in the surrogate do not reliably lead to changes in the associated patient-important outcome.[14] This limits the strength of inferences from such studies.

Many of the questions listed above address issues within the "clinical episode," but the evaluation of the longer-term value or benefit of a diagnostic test is more complex. Long-term costs and benefits, as in management of a chronic condition such as diabetes, may be influenced by other (confounding) factors. The complexity depends on the rela-

tionship between test and treatment and also on the compliance of both patient and clinician in use of both the test and the treatment. In diabetes, the measurement of blood glucose and HbA_{1c} is an integral part of management. Although short-term studies have been done,[39] rigorous economic evaluations of the long-term use of these tests are rare. Economic modeling of both the Diabetes Control and Complications Trial (DCCT) and United Kingdom Prospective Diabetes Study (UKPDS) demonstrated the economic benefits of intensive glycemic control[20,38] but did not indicate the value of the testing component. An observational study of the implementation of an intensive glycemic control program demonstrated long-term savings from improved clinical outcomes that reduced clinic visits and hospital admissions and their attendant costs.[97]

Use of Economic Evaluations in Decision Making

The stream of new tests in laboratory medicine requires frequent decisions about whether or not to implement them. Economic evaluations can help in making these decisions. The finite resources for healthcare require use of an objective means of determining how resources are allocated and how the efficiency and effectiveness of service delivery can be improved.

Use of economic evaluations faces several challenges. First, the laboratory medicine budget is usually "controlled" independently of the other costs of healthcare. This is often referred to as "silo budgeting." In practical terms the budget for testing is established independently of the budgets for all of the other services, including budgets for which the contemplated diagnostic test might be able to provide savings. Second, achievement of a favorable outcome (e.g., from a reduction in length of stay or a decrease of admissions to the coronary care unit) is of use from a management standpoint only if the potential savings can be turned into real money (leveraged). Third, the introduction of a new test or testing modality (e.g., POCT) will undoubtedly lead to a change in practice and so the benefits can be achieved only if the change in practice can be implemented. Finally, even if the desired cost savings are achieved, silo budgeting ensures that the savings are seen in a budget different from the laboratory's, and the laboratory budget shows only an increased cost. Fortunately the drawbacks of silo budgeting are being recognized, and a broader view of health economics seems to be developing in some healthcare settings.

Regardless of any problems in introducing them, economic evaluations can provide the objective measure of what can be achieved, and the standard against which the change in practice can be audited after implementation.

CLINICAL PRACTICE GUIDELINES

The patient-centered goals of evidenced-based laboratory medicine cannot be reached by primary studies and systematic reviews alone. The results of these investigations must be turned into action. Increasingly, health systems and professional groups in medicine have turned to the use of clinical practice guidelines as one tool to facilitate implementation of lessons from primary studies and systematic reviews. Important motivations for development of guidelines have been to decrease variability in practice (and improve the use of best practices) and to decrease the (often prolonged) time required for new information to be used for the benefit of patients for prevention of disease.

Although most guidelines have been developed primarily for use by clinicians, publication of guidelines on the Internet, and descriptions of them in articles in the popular press, have led to their use by patients and their families.[13] The development of such guidelines is a challenging new area about which some things are becoming clearer, including the absence of tested guidelines for the development of laboratory-related guidelines. A start in this direction for laboratory medicine has appeared recently.[71]

What Is a Clinical Practice Guideline?

A widely quoted definition of clinical practice guidelines comes from a report of the U.S. Institute of Medicine. "Clinical practice guidelines are systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances."[31] This definition appears broad enough to accommodate the laboratory-related guidelines that are appearing in the literature and on the Internet. Guidelines of various sorts have long addressed issues of concern to laboratorians, such as requirements or goals for accuracy, precision, and turnaround time of tests and considerations about the frequency of repeat tests in the monitoring of patients. In contrast to many earlier pronouncements on such issues, the focus of modern clinical practice guidelines, such as recent ones on laboratory testing in diabetes[83] and liver disease,[24,25] is the patient in the "specific clinical circumstances" referred to in the definition of clinical practice guidelines. The new ingredient in development of these guidelines is the tool kit of EBM and clinical epidemiology, which allow the guidelines to grow in a more transparent way from well-conducted studies and systematic reviews.

A Transparent Process Must Be Used in the Development of Guidelines

In the absence of a transparent process for development of a guideline, the credibility of the product is compromised and can be legitimately questioned. When guidelines are developed by a professional group (such as specialist physicians or laboratory-based practitioners), the recommendations (e.g., to perform a diagnostic procedure in a given setting) may be suspected of promoting the welfare of the professional group. By contrast, when guidelines are prepared under the auspices of payers for healthcare (governments and insurance companies), the recommendations may be seen as cost-control measures. In this setting, a key danger is that the absence of evidence of a benefit from a

medical intervention may be interpreted as evidence of absence of benefit.

Steps in the Development of Guidelines

The development of guidelines is best undertaken with a step-by-step plan. One such scheme is shown in Figure 13-6, only selected issues of which will be discussed here. For a more detailed discussion, see Bruns and Oosterhuis[13] or Oosterhuis et al.[71]

Selection and Refinement of a Topic

The critical importance of this first step is analogous to the importance of the corresponding step in development of a systematic review. The scope must not exceed the capabilities (in time, funding, and expertise) of the group, the topic must not be without evidence (or the guideline will lack credibility), and the area must be one requiring attention (or the guideline will have little value and will attract no attention).

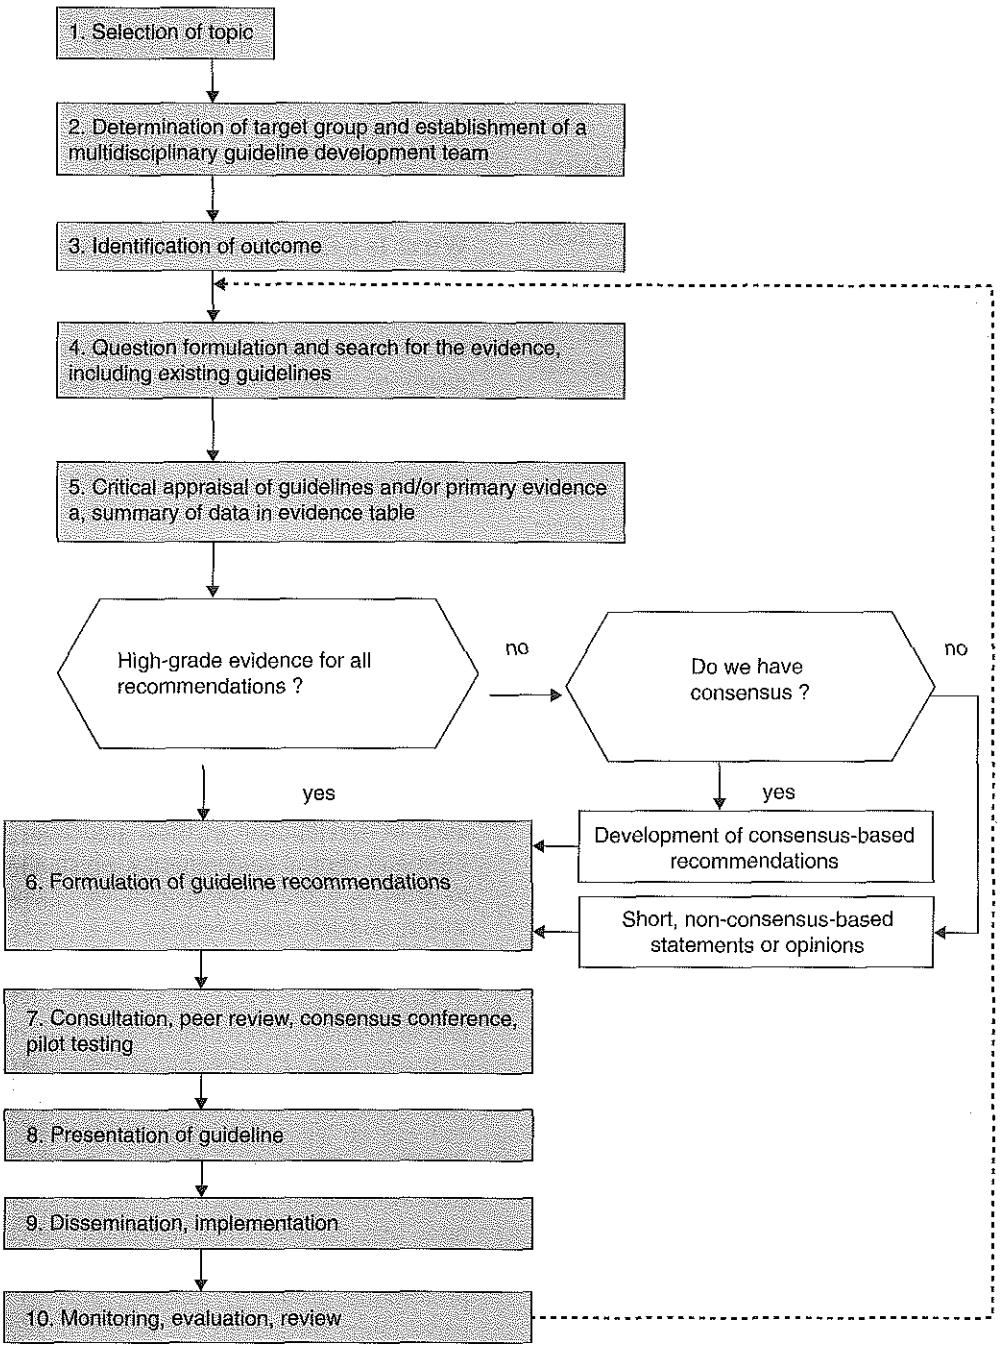

Figure 13-6 Steps in development of a clinical practice guideline. *(Modified from Oosterhuis WP, Bruns DE, Watine J, Sandberg S, Horvath AR. Evidence-based guidelines in laboratory medicine: principles and methods. Clin Chem 2004;50: 806-818.)*

Guidelines can address clinical conditions (such as diabetes and liver disease), symptoms (chest pain), signs (abnormal bleeding), or interventions, whether therapeutic (coronary angioplasty and aspirin) or diagnostic (cardiac markers). The priority for a guideline should be: Is there variation in practice that suggests uncertainty? Is the issue of public health importance, such as in the increasing problem of diabetes and obesity? Is there a perceived necessity for cost reduction?

The critical issues to be addressed must be identified and distinguished from those that may be considered peripheral or simply beyond the scope that can reasonably be included. Ideally, this process involves a multidisciplinary group, with clinicians, laboratory experts, patients, and likely users of the guidelines. The scope will be affected by the staff (if any) and financial support available to the guideline group. The cost is usually underestimated.

Determination of Target Group and Establishment of a Multidisciplinary Guideline Development Team

The intended audience must be identified: Is it nurses, general practice physicians, clinical specialty physicians, laboratory specialists, or patients?

The team should include representatives of all key groups involved in the management of the target condition. In development of guidelines in laboratory medicine, teams ideally include relevant medical specialists, laboratory experts, methodologists (for expertise in statistics, literature search, critical appraisal, and guideline development), and those who deliver services (such as nurse practitioners and patients for guidelines on home monitoring of glucose; laboratory technicians and managers for a guideline that addresses turnaround times for cardiac markers).

As the composition of guideline development groups affects recommendations, with those who perform procedures more likely to recommend their use,[55] potential conflicts of interest of all members must be noted. The role if any of sponsors (commercial or nonprofit) in the guideline development process must be agreed upon and reported. Ideally, staff support is available for arranging meetings and conference calls and assisting with publication and other forms of dissemination (e.g., audioconferences).

A minimum group size of six has been recommended.[88] Making the team larger than 12 to 15 persons can inhibit the airing of each person's views. A recommended tool is the use of subgroups to focus on specific questions, with a steering committee responsible for coordination and the production of the final guideline. Other ways of using subgroups can be envisioned.

Identifying and Assessing the Evidence

When available, well-performed systematic reviews form the most important part of the evidence base for guidelines. Systematic reviews are necessary when there is expected to be variation between studies, sometimes attributable to effects too small to be measured. Where no systematic reviews exist, the group effectively must undertake to produce one. The level of evidence supporting each conclusion in the review will affect the recommendations made in the guidelines.

Translating Evidence into a Guideline and Grading the Strength of Recommendations

The processes for reaching recommendations within an expert group are poorly understood. For clinical practice guidelines, the process may involve balancing of costs and benefits after values are assigned and the strength of evidence is weighed. Conclusive evidence for recommendations is only rarely available. Authors of guidelines thus have an ethical responsibility to make very clear the level of evidence that supports each recommendation.

Various schemes are available for grading the level of evidence, and one of them should be adopted and used explicitly.[13,71] A rather simple one, with a rather typical four levels (A through D), is shown in Table 13-3. More complex schemes are shown in Tables 13-4 and Box 13-2. For a recent and different approach, see the additional readings at the end of this chapter. The level of evidence does not always predict the strength of a recommendation, as recommendations may either follow directly from clinical studies or be extrapolated from the results of the studies. For example, multiple studies supporting use of a drug may have been done well and a competent systematic review may be available, so that the evidence may be graded as high. However if the study was done in adults and the guideline is for children, the strength of the recommendation may be low.[13]

TABLE 13-3 A Scheme for Grading of Strength of Recommendations in Clinical Guidelines

Level	Characteristics
A	Directly based on meta-analysis of RCTs or on at least one RCT
B	Directly based on at least one controlled study without randomization or at least one other type of quasiexperimental study, or extrapolated from RCTs
C	Directly based on nonexperimental studies or extrapolated from RCTs or nonrandomized studies
D	Directly based on expert reports or opinion or experience of authorities, or extrapolated from RCTs, nonrandomized studies, or nonexperimental studies

From Shekelle PG, Woolf SH, Eccles M, Grimshaw J. Clinical guidelines: developing guidelines. BMJ 1999; 318: 593-6.

TABLE 13-4 Categories of Evidence Supporting Guidelines (A-E) and Quality of Evidence on Which Recommendation Is Based (I-IV) as Used by the American Association for the Study of Liver Disease

Category	Explanation
I	Evidence from multiple well-designed randomized controlled clinical trials, each involving a number of patients to be of sufficient statistical power
II	Evidence from at least one large well-designed clinical trial with or without randomization, from cohort or case-controlled analytical studies, or well-designed meta-analysis
III	Evidence based on clinical experience, descriptive studies, or reports of expert committees
IV	Not rated
A	Survival benefit
B	Improved diagnosis
C	Improvement in quality of life
D	Relevant pathophysiological parameters improved
E	Impacts cost of healthcare

From Dufour DR, Lott JA, Nolte FS, Gretch DR, Koff RS, Seeff LB. Diagnosis and monitoring of hepatic injury. II. Recommendations for use of laboratory tests in screening, diagnosis, and monitoring. Clin Chem 2000;46:2050-68.

BOX 13-2 System to Rate the Strength of a Body of Evidence

Quality of Primary Studies and Reviews: Rating the Level of Evidence of Individual Articles:

- Ia Meta-analysis or systematic review based on at least several level Ib studies
- Ib Diagnostic trial or outcome study of good quality
- II Diagnostic trial or outcome study of medium quality, insufficient patients, or other trials (case-control, other designs)
- III Descriptive studies, case reports, other studies
- IV Statements of committees, opinion of experts etc., review, not systematic

Rating of the Strength of the Evidence Supporting Guideline Recommendations:

- A Supported by at least two independent studies of level Ib or one review of level Ia ("it was shown/demonstrated")
- B Supported by at least two independent studies of level II ("it is plausible")
- C Not supported by sufficient studies of level I or II ("indications"), poorly
- D Advice of experts, etc. ("there is no proof")

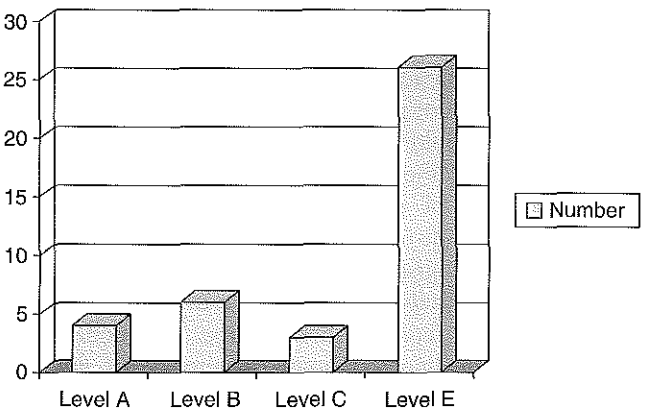

Figure 13-7 Level of evidence for recommendations in NACB guideline for testing in diabetes.[83] *(From Bruns DE, Oosterhuis WP in Price CP, Christenson RH, eds Evidence-Based Laboratory Medicine: from principles to outcomes. AACC Press, 2003.)*

Level A evidence is rare in guidelines on the use of diagnostic tests. The recommendations made in the National Academy of Clinical Biochemistry (NACB) guidelines on laboratory testing in diabetes[83] were graded by the scheme of the American Diabetes Association, a scheme similar to that in Table 13-3 except that level D is referred to as level E. As shown in Figure 13-7, the vast majority of the recommendations were graded only as level E (expert opinion) by the authors of the guidelines, and only three were graded as A. The high proportion of recommendations in the NACB document supported only by expert opinion is far from unique or peculiar to that document or to guidelines for diagnostic tests.

For analytical goal setting or "quality specifications" for analytical methods in guidelines, randomized controlled clinical trials (outcomes studies) are rarely available. As discussed by Bruns and Oosterhuis,[13] a different hierarchy of evidence[32] (Table 13-5) may be useful for grading of such laboratory-related recommendations. The highest level of evidence is evidence related to medical needs. It is conceivable that even statistical modeling of specific clinical decisions could be considered as a subtype of evidence related to medical needs. For example, Klee et al[52] have shown rates of misclassification of cardiac risk as a function of analytical bias of cholesterol assays. Similarly, error rates in insulin dosing can be calculated[10] as a function of imprecision (or bias or both) of home glucose measurements, with increas-

TABLE 13-5 Hierarchy of Criteria for Quality Specifications

Level	Basis
1A	Medical decision making: Use of test in specific clinical situations
1B	Medical decision making: Use of test in medicine generally
2	Guidelines—"experts"
3	Regulators or organizers of external quality assurance schemes
4	Published data on state of the art

From Fraser CG, Petersen PH. Analytical performance characteristics should be judged against objective quality specifications. Clin Chem 1999;45:321-3.

ing imprecision (or bias) of the glucose assay leading to increasingly frequent errors in the administered dose of insulin. Although such studies do not demonstrate an effect on patient outcomes, they may be a distinct advance over anecdotes, and an expert group can make reasoned recommendations for imprecision based on such data and mathematical modeling when the clinical action follows a well-defined rule.

Level 1B in Table 13-5 refers primarily to the concepts of *within-person and among-person biological variation*. Levels of optimum, desirable, and minimum performance for both imprecision and bias have been defined[32] based on these concepts. When a test is to be used for monitoring, use of this type of quality specification for imprecision appears appropriate in guidelines. Failure to use this approach is difficult to justify, because data on within-person and among-person biological variation are available for virtually all commonly used tests. The quality specifications relate directly to the ability to use assays for monitoring and the ability to use common reference intervals within a population. These may be considered patient-centered objectives in a broad sense if not in a narrow one.

Obtaining External Review and Updating the Guidelines

Three types of outside examiners can evaluate the guideline[88]:

- Experts in the clinical content area—to assess completeness of literature review and the reasonableness of recommendations
- Experts on systematic reviewing and guideline development—to review the process of guideline development
- Potential users of the guidelines

In addition, journals, sponsoring organizations, and other potential endorsers of the guidelines may undertake formal reviews. Each of these reviews can add value.

As part of the guideline development process, a plan for updating should be developed. The importance of this step

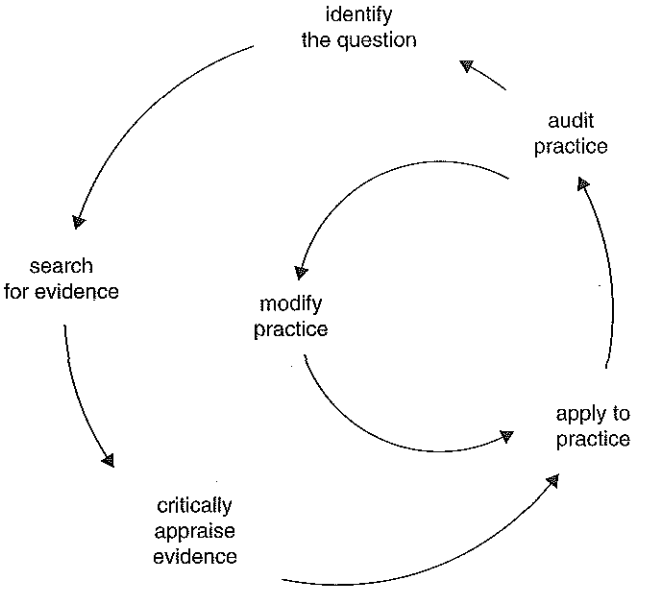

Figure 13-8 The audit cycle. *(From Price CP. Clin Chem 2000;46:1041-50.)*

is underscored by the finding that one of the most common reasons for nonadherence to guidelines is that the guidelines are outdated.[96] Consistent with that finding, a study[87] of clinical practice guidelines of the Agency for Healthcare Research and Quality showed that about half the guidelines were outdated in 5.8 years (95% confidence interval [CI] 5.0 to 6.6 years). No more than 90% of conclusions were still valid after 3.6 years (CI 2.6 to 4.6 years). These findings suggest that the time interval between completion and review of a guideline should be short.

CLINICAL AUDIT

The term "audit" is associated with a particular connotation in healthcare, namely clinical audit and refers to the review of case histories of patients against the benchmark of current best practice.[86] The clinical audit was proposed as a tool to improve clinical practice and a recent study indicates that it can do so, though the effects are modest.[93] A more general role for audit, however, is that it can be used as part of the wider management exercise of benchmarking of performance with the use of relevant performance indicators against the performance of peers.

Four distinct activities can be considered under the broad umbrella of an audit: (1) solving problems associated with the process or outcome, (2) monitoring workload in the context of controlling demand, (3) monitoring the introduction of a new test and/or changes in practice, and (4) monitoring the adherence with best practices (e.g., with guidelines).

The components of the audit cycle are depicted in Figure 13-8. All of the audit activities are found in the practice of evidence-based laboratory medicine, namely that there is a

clinical question for which the test result should provide an answer and that the answer will lead to a decision being made and an action taken, leading to an improved health outcome. There should be evidence to support the use of the test in the setting for which it is being used.

Audit to Help Solve Problems

All audits involve the collection of observational data and comparison against a standard or specification. In many cases a standard does not exist, and maybe not even a specification; then it is important to establish a specification as the first stage of auditing a process. Such a specification may then generate observations, which can lead to the creation of a standard. At the outset it provides the comparative measure against which to judge the performance data collected.

Solving a problem relating to a process may first involve collecting data on aspects of the process that are considered to have an influence on the outcome with the goal of identifying rate-limiting steps. For example, a study of test result turnaround times might collect data on phlebotomy waiting time, quality of patient identification, transport time, sample registration time, quality of sample identification, sample preparation time, analysis time, test result validation time, and result delivery time.

The study of process may extend to the way in which the results are accessed and used. For example, the use of POCT in an emergency department (not in an audit) did not decrease the length of stay despite the fact that the delivery time for the results was much shorter than when results were provided by the laboratory.[48] The authors concluded that the test result was not the rate-limiting step.[48] Murray, in a similar study,[66] did find a reduction in the length of stay and identified a subset of patients in which the POCTs could be used to rule out diagnoses and allow a faster discharge. They noted that in other cases the triage decision was delayed by the need for results from the laboratory.

Monitoring Workload and Demand

The true demand for a test will depend on the number of patients and the spectrum of disease in each case where the test is appropriate. The appropriateness of the test request is a valuable arbiter in situations in which workload or demand for tests is questioned. A portfolio of evidence helps to define the basis for the appropriate use of tests. When conducting an audit of workload for a test it is possible to ask a number of questions, usually by questionnaire that are directly related to the original generation of the evidence upon which the use of the test should be based (guidelines). These include:

- What clinical question is being asked?
- What decision will be aided by the results of the test?
- What action will be taken following the decision?
- What risks are associated with not receiving the result?
- What are the expected outcomes?
- Is there evidence to support the use of the test in this setting?
- And, for tests ordered urgently, why was this test result required urgently?

This approach is likely to identify unnecessary use of tests, misunderstandings about the use of tests, and instances of use of the wrong test. With the advent of electronic requesting and the electronic patient record, it is possible to build this approach into a routine practice.

After receipt of the results from the questionnaire, a number of actions may follow depending on the findings from the survey. They are likely to include (1) feedback of results to the users, (2) reeducation of users, (3) identification of unmet needs and research to satisfy, for example, a need for advice on alternative test, (4) creation of an algorithm or guideline on use of the test, and (5) reaudit in 6 months time to review for change in practice. Any algorithm may be embedded in the electronic requesting package to provide an automatic bar to inappropriate requesting (e.g., to prevent liver function tests from being requested every day).

Monitoring the Introduction of a New Test

In this situation the main objectives of the audit are to ensure (1) that the change in practice that is often consequent upon the introduction of a new test has been effected, and (2) that the outcomes originally predicted are being delivered. The development of any new test should lead to evidence that identifies the way in which the test is going to be used, including:

- Identification of the clinical question(s), patient cohort, clinical setting, etc.
- Identification of preanalytical and analytical requirements for the test
- Identification of any algorithm into which the test might have to be inserted (e.g., use in conjunction with other tests, signs, or symptoms)
- Identification of the decision(s) that is likely to be made on receipt of the result
- Identification of the action(s) likely to be taken on receipt of the result
- Identification of the likely outcome(s)
- Identification of any risks associated with introduction of a new test
- The evidence (and strength of that evidence) that supports the use of the test and the outcomes to be expected
- Identification of any changes in practice (e.g., deletion of another test from the repertoire, move to POCT, and reduction in laboratory workload)

This "summary of use" and portfolio of evidence forms the basis of the "standard operating procedure" for the clinical use of the test, the core of the educational material for users of the service, and the basis for conducting the audit.

Before auditing, the introduction of a new test is obviously important to have ensured that a full program of education of users has been completed and that any other changes in practice have been accommodated in the clinic and/or ward routines. Thus if a test is moving to the point-

of-care then there has to have been the necessary training and certification of operators completed.

Monitoring Adherence to Best Practice

This is the scenario that probably best reflects the way in which the "clinical audit" was first envisaged and practiced. Typically, it is based on the review of randomly selected cases from a clinical team with the review undertaken by an independent clinician. This approach is the most likely to identify when a test has not been performed and identifying unnecessary testing. The audit is best performed against some form of benchmark, which may be a local, regional, or national guideline; the existence of a guideline appropriately written (see earlier) will have taken into account the best evidence available and in so doing takes away any bias that may exist between clinical teams.

In recent years registers have been established to track the performance of health institutions and organizations. Typically, such registers are disease specific and will measure outputs at a high level (e.g., morbidity and mortality).[17,28,35] In some cases (e.g., the UK Renal Registry[92]), the data collected are extensive and include laboratory information. This depth of data is extremely helpful to the laboratory specialist because it begins to provide a basis for looking at issues, such as the impact of the analytical performance of certain tests on clinical outcomes.

APPLYING THE PRINCIPLES OF EVIDENCE-BASED LABORATORY MEDICINE IN ROUTINE PRACTICE

It is hopefully clear from the foregoing discussion that the principles of evidence-based laboratory medicine can underpin the way in which laboratory medicine is practiced, from the discovery of a new diagnostic test through to its application in routine patient care. The principles provide the logic on which all of the elements of practice are founded. The tools of evidence-based laboratory medicine provide the means of delivering the highest quality of service in meeting the needs of patients and the healthcare professionals who serve them. The application of evidence-based practice is far more complex in the case of laboratory medicine than in the major area in which such principles have previously been applied, namely the pharmaceutical intervention.

The ways in which the test is used, once its efficacy has been demonstrated, will be embodied in the laboratory handbook which, increasingly, will be electronic, fully searchable in real time, and built into clinical protocols and care pathways. Such a handbook can then be supported by an information resource, again searchable, which will inform the clinician (and the patient) of the strength of evidence to support the use of the test in a specific situation. Use of these resources is practical as shown by Richardson and Burdette, who observed that information resources could be accessed during patient consultations, with each access completed in 4 to 5 seconds.[78]

The demonstration of improved outcomes in addition to providing a validation of the test also provides the data on which to undertake some form of economic analysis. As indicated earlier, this will show where the benefits are generated and what the costs and savings will be—costs to the laboratory medicine budget and savings elsewhere in the health economy. This information will enable a business case to be produced, supporting a reimbursement strategy—the style of which will depend on the type of healthcare system. The real challenge, however, comes in identifying the changes in practice, which will undoubtedly have to be implemented should the test be introduced (e.g., to leverage the benefits from reduction in length of stay, faster optimization of therapy, earlier discharge, and rule-out decisions in primary care).

The evidence base then underpins the activities that ensure the maintenance of a high quality of service: (1) provision of a knowledge resource that summarizes the evidence and its application, (2) use of this resource in education and training of health professionals, and (3) audit to ensure correct implementation and maintenance of good practice.

EBM expects clinicians to turn to primary studies of diagnostic performance and outcomes to guide decision making. However, as has been observed during the course of this chapter, there are few such studies available for diagnostic tests and devices. Furthermore in the case of many tests it will be difficult to undertake such studies as use of the markers has become embedded in routine practice and consensus guidelines. In these cases it will be necessary to depend on a more audit style of evaluation to attempt to validate the use of a test. Although this may appear as a limitation it still embodies many of the principles of evidence-based practice in laboratory medicine; crucially, recognition of the question for which the test result is seeking to provide an answer. Furthermore, the focus on outcomes will certainly help to demonstrate the value of the laboratory medicine service.

CHAPTER 14

Selection and Analytical Evaluation of Methods—With Statistical Techniques

*Kristian Linnet, M.D., and James C. Boyd, M.D.**

The introduction of new or revised methods is a common occurrence in the clinical laboratory. Method selection and evaluation are key steps in the process of implementing new methods (Figure 14-1). A new or revised method must be selected carefully, and its performance evaluated thoroughly in the laboratory before being adopted for routine use. The establishment of a new method may also involve an evaluation of the features of the automated analyzer on which the method will be implemented.

Method evaluation in the clinical laboratory is influenced strongly by guidelines. The National Committee for Clinical Laboratory Standards (NCCLS) has published a series of consensus protocols[76-81] for clinical chemistry laboratories and manufacturers to follow when evaluating methods (see the NCCLS website http://nccls.org). The International Organization for Standardization (ISO) has also developed several documents related to method evaluation.[34-43] In addition, meeting laboratory accreditation requirements has become an important aspect in the method selection and/or evaluation process. In recent years, accrediting agencies have placed increased focus on the importance of total quality management and assessment of trueness and precision of laboratory measurements. An accompanying trend has been the emergence of an international nomenclature to standardize the terminology used for characterizing method performance. This chapter presents an overview of considerations in the method selection process, followed by sections on method evaluation and method comparison. The latter two sections focus on graphical and statistical tools that are used to aid in the method evaluation process, provide examples of the application of these tools, and summarize current terminology within the area.

*The authors gratefully acknowledge the original contributions by David D. Koch, Theodore Peters, Jr., Robert O. Kringle, and Mike Bogovich, on which portions of this chapter are based.

METHOD SELECTION

Optimal method selection involves consideration of medical, analytical performance, and practical criteria.

Medical Criteria

The selection of appropriate methods for clinical laboratory assays is a vital part of rendering optimal patient care, and advances in patient care are frequently based upon the use of new or improved laboratory tests. Ascertainment of what is necessary clinically from a laboratory test is the first step in selecting a candidate method (Figure 14-1). Key parameters such as desired turnaround time and necessary clinical utility for an assay can often be derived by discussions between laboratorians and clinicians. When introducing new

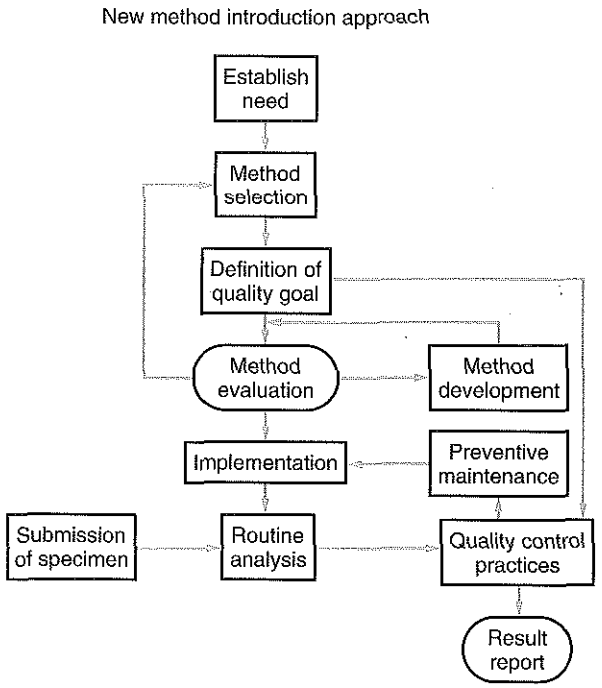

Figure 14-1 A flow diagram that illustrates the process of introducing a new method into routine use. The diagram highlights the key steps of method selection, method evaluation, and quality control.

diagnostic assays, reliable estimates of clinical sensitivity and specificity must be obtained either from the literature or by conducting a clinical outcome study (see Chapter 15). With established analytes, a common scenario is the replacement of an older, labor-intensive method with a new, automated assay that is more economical in daily use. In these situations, consideration must be given to whether the candidate method has sufficient precision, accuracy, analytical measurement range, and freedom from interference to provide clinically useful results.

Analytical Performance Criteria

In evaluation of the performance characteristics of a candidate method, precision, accuracy (trueness), analytical range, detection limit, and analytical specificity are of prime importance. The sections in this chapter on method evaluation and comparison contain a detailed outline of these concepts and their assessment. The estimated performance parameters for a method can then be related to quality goals that ensure acceptable medical use of the test results (see section on Analytical Goals). From a practical point of view, the "ruggedness" of the method in routine use is of importance. Reliable performance when used by different operators and with different batches of reagents over longer time periods is essential.

When a new clinical analyzer is included in the overall evaluation process, various instrumental parameters also require evaluation, including pipetting precision, specimen-to-specimen carryover and reagent-to-reagent carryover, detector imprecision, time to first reportable result, onboard reagent stability, overall throughput, mean time between instrument failures, and mean time to repair. Information on most of these parameters should be available from the instrument manufacturer, and the manufacturer should also be able to furnish information on what user studies to conduct in estimating these parameters for an individual analyzer.

Other Criteria

Various categories of candidate methods may be considered. New methods described in the scientific literature may require "in-house" development. Commercial kit methods, on the other hand, are ready for implementation in the laboratory, often in a "closed" analytical system on a dedicated instrument. When reviewing prospective methods, attention should be given to the following:

1. The principle of the assay, with original references
2. The detailed protocol for performing the test
3. The composition of reagents and reference materials, the quantities provided, and their storage requirements (e.g., space, temperature, light, and humidity restrictions) applicable both before and after opening the original containers
4. The stability of reagents and reference materials (e.g., their shelf life)
5. Technologist time and required skills
6. Possible hazards and appropriate safety precautions according to relevant guidelines and legislation
7. The type, quantity, and disposal of waste generated
8. Specimen requirements (i.e., conditions for collection, specimen volume requirements, the necessity for anticoagulants and preservatives, and necessary storage conditions)
9. The reference interval of the method, including information on how it was derived, typical values obtained in health and disease, and the necessity of determining a reference interval for one's own institution (see Chapter 16 for details on how to generate a reference interval)
10. Instrumental requirements and limitations
11. Cost effectiveness
12. Computer platforms and interfacing to the laboratory information system
13. The availability of technical support, supplies, and service

Other questions concerning placement of the method in the laboratory should be taken into account. Does the laboratory possess the necessary measuring equipment? If not, is there sufficient space for a new instrument? Does the projected workload match with the capacity of a new instrument? Is the test repertoire of a new instrument sufficient? What is the method and frequency of calibration? Is the staffing of the laboratory sufficient for the new technology? If training the entire staff in a new technique is required, is

such training worth the possible benefit? How frequently will quality control samples be run, and what materials will be used for quality control? What approach will be used with the method for proficiency testing? What is the estimated cost of performing an assay using the proposed method, including the cost of calibrators, quality control specimens, and technologists' time?

Questions applicable to implementation of new instrumentation in a particular laboratory may also be relevant. Does the instrument on which the method is implemented satisfy local electrical safety guidelines? What are the power, water, drainage, and air-conditioning requirements of the instrument? If the instrument is large, does the floor have sufficient load-bearing capacity?

A qualitative assessment of the above factors is often made, but it is also possible to use a value scale to assign points to the various features of a method weighted according to their relative importance; the latter approach allows a more quantitative selection process. Decisions can then be made regarding the analytical methods that best fit the laboratory's requirements and that have the potential for achieving the necessary analytical quality.

BASIC CONCEPTS IN RELATION TO ANALYTICAL METHODS

This section defines the basic concepts used in this chapter (e.g., calibration, accuracy, precision, linearity, limit of detection, and others).

CALIBRATION

The calibration function is the relation between instrument signal (y) and concentration of analyte (x) i.e.,

$$y = f(x)$$

The inverse of this function, also called the measuring function, yields the concentration from response:

$$x = f^{-1}(y)$$

This relationship is established by measurement of samples with known amounts of analyte (calibrators).[14] One may distinguish between solutions of pure chemical standards and samples with known amounts of analyte present in the typical matrix that is to be measured (e.g., human serum). The first situation applies typically to a reference measurement procedure, which is not influenced by matrix effects, and the second case corresponds typically to a field method that often is influenced by matrix components and so preferably is calibrated using the relevant matrix.[90] Calibration functions may be linear or curved, and in the case of immunoassays often of a special form (e.g., modeled by the four-parameter logistic curve).[92] This model (logistic in log x) has been used for both radioimmunoassay and enzyme immunoassay techniques and can be written in several forms as shown (Table 14-1). Nonlinear regression analysis is applied to estimate the relationship, or a logit transformation to a linear form is carried out. An alternative, model-free approach is to estimate a smoothed spline curve, which often is performed for immunoassays. The only requirement is that there should be a monotonic relationship between signal and analyte concentration over the analytical measurement range. Otherwise the possibility of errors occurs (e.g., the hook effect in immunoassays) caused by a decreasing signal response at very high concentrations. If the assumed calibration function does not correctly reflect the true relationship between instrument response and analyte concentration, a systematic error or bias is likely to be associated with the analytical method. A common problem is deviation from linearity in the high concentration range.

TABLE 14-1 The Four-Parameter Logistic Model Expressed in Three Different Forms

Algebraic Form	Variables*	Parameters†
$y = (a - d)/[1 + (x/c)^b] + d$	(x, y)	a, b, c, d
$R = R_0 + K_c/(1 + \exp[-(a + b\log(C))])$	(C, R)	R_0, K_c, a, b
$y = y_0 + (y_\infty - y_0)(x^d)/(b + x^d)$	(x, y)	y_0, y_∞, b, d

*Concentration and instrument response variables shown in parentheses.
†Equivalent letters do not necessarily denote equivalent parameters.

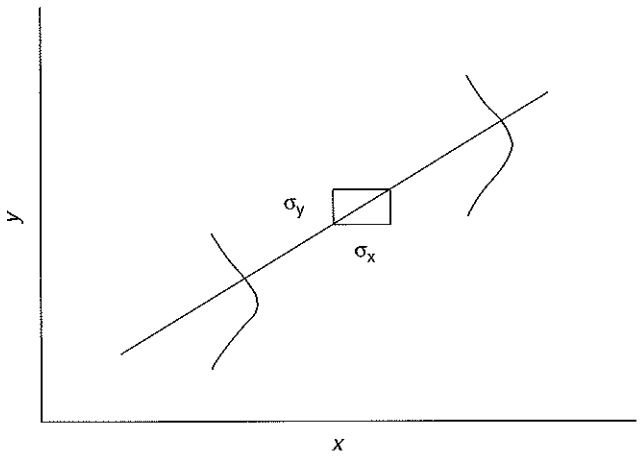

Figure 14-2 Relation between concentration (x) and signal response (y) for a linear calibration curve. The dispersion in signal response (σ_y) is projected onto the x axis giving rise to assay imprecision (σ_x).

The precision of the analytical method depends on the stability of the instrument response for a given amount of analyte. In principle, a random dispersion of instrument signal at a given concentration transforms into dispersion on the measurement scale as schematically shown (Figure 14-2). The detailed statistical aspects of calibration are rather complex,[95,97] but in the following, some approximate rela-

TABLE 14-2 An Overview of Qualitative Terms and Quantitative Measures Related to Method Performance

Qualitative Concept	Quantitative Measure
Trueness Closeness of agreement of mean value with "true value"	**Bias** A measure of the systematic error
Precision Repeatability (within run) Intermediate precision (long term) Reproducibility (interlaboratory)	**Imprecision (SD)** A measure of the dispersion of random errors
Accuracy Closeness of agreement of a single measurement with "true value"	**Error of Measurement** Comprises both random and systematic influences

tions are outlined. If the calibration function is linear, and the imprecision of the signal response is the same over the analytical measurement range, the analytical standard deviation (SD_A) of the method tends to be constant over the analytical measurement range (Figure 14-2). If the imprecision increases proportionally to the signal response level, the analytical SD of the method tends to increase proportionally to the concentration level (x), which means that the *relative* imprecision (coefficient of variation, [CV] = SD/x) is constant over the analytical measurement range—supposing that the intercept of the calibration line is zero. In the case of nonlinear calibration curves, the precision often varies over the analytical measurement range, being best at the steepest part of the calibration curve, at least if the imprecision of the signal is the same over the analytical measurement range (see also the Analytical Sensitivity section in this chapter).

In modern automated clinical chemistry instruments, the relation between analyte concentration and signal is often very stable so that calibration is necessary infrequently (e.g., at intervals of several months).[89] Built-in process control mechanisms may help ensure that the relationship remains stable and indicate when recalibration is necessary. In traditional chromatographic analysis (e.g., high-performance liquid chromatography [HPLC]), on the other hand, it is customary to calibrate each analytical series (run), which means that calibration is carried out daily. Aronson et al[2] established a detailed simulation model of the various factors influencing method performance with focus on the calibration function.

Trueness and Accuracy

Trueness of measurements is defined as closeness of agreement between the average value obtained from a large series of results of measurements and a true value.[21,37] The difference between the average value (strictly, the mathematical expectation) and the true value is the *bias*, which is expressed numerically and so is inversely related to the trueness. Trueness in itself is a qualitative term that can be expressed as, for example, low, medium, or high. From a theoretical point of view, the exact true value is not available, and instead an "accepted reference value" is considered, which is the "true" value that can be determined in practice.[21] Trueness can be evaluated by comparison of measurements by a given (field) method and a reference method. Such an evaluation may be carried out by parallel measurements of a set of patient samples or by measurements of reference materials (see traceability and uncertainty). The ISO has introduced the trueness expression as a replacement for the term "accuracy," which now has gained a slightly different meaning. *Accuracy* is the closeness of the agreement between the result of a measurement and a true concentration of the analyte.[37] Accuracy is thus influenced by both bias and imprecision and in this way reflects the total error. Accuracy, which in itself is a qualitative term, is inversely related to the "uncertainty" of measurement, which can be quantified as described later (Table 14-2).

In relation to trueness, the concepts *recovery, drift,* and *carryover* may also be considered. Recovery is the fraction or percentage increase of concentration that is measured in relation to the amount added. Recovery experiments are typically carried out in the field of drug analysis. One may distinguish between *extraction recovery,* which often is interpreted as the fraction of compound that is carried through an extraction process, and the recovery measured by the entire analytical procedure, in which the addition of an internal standard compensates for losses in the extraction procedure. A recovery close to 100% is a prerequisite for a high degree of trueness, but it does not ensure unbiased results, because possible nonspecificity against matrix components is not detected in a recovery experiment. *Drift* is caused by instrument instability over time, so that calibration becomes biased. Assay *carryover* also must be close to zero to ensure unbiased results. Drift or carryover or both may be conveniently estimated by multifactorial evaluation protocols[52] (see the NCCLS guideline EP10-A2, *Preliminary evaluation of quantitative clinical laboratory methods*).[77]

PRECISION

Precision may be defined as the closeness of agreement between independent results of measurements obtained under stipulated conditions.[21] The degree of precision is usually expressed on the basis of statistical measures of imprecision, such as the SD or CV (CV = SD/x, where x is the measurement concentration), which thus is inversely related to precision. Imprecision of measurements is solely related to the random error of measurements and has no relation to the trueness of measurements.

Precision is specified as follows[21,35]:

Repeatability: closeness of agreement between results of successive measurements carried out under the same conditions (i.e., corresponding to within-run precision).

Reproducibility: closeness of agreement between results of measurements performed under changed conditions of measurements (e.g., time, operators, calibrators, and reagent lots). Two specifications of reproducibility are often used: total or between-run precision in the laboratory, often termed *intermediate precision,* and interlaboratory precision (e.g., as observed in external quality assessment schemes [EQAS]) (see Table 14-2).

The total standard deviation (σ_T) may be split into within-run and between-run components using the principle of analysis of variance components (variance is the squared SD):[97]

$$\sigma_T^2 = \sigma_{\text{Within-run}}^2 + \sigma_{\text{Between-run}}^2$$

It is not always clear in clinical chemistry publications what is meant by "between-run" variation. Some authors use the term to refer to the total variation of an assay, whereas others apply the term between-run variance component as defined above. The distinction between these definitions is important but is not always explicitly stated.

In laboratory studies of analytical variation, it is *estimates* of imprecision that are obtained. The more observations, the more certain are the estimates. Commonly the number 20 is given as a reasonable number of observations (e.g., suggested in the NCCLS guideline on the topic).[76] To estimate both the within-run imprecision and the total imprecision, a common approach is to measure duplicate control samples in a series of runs. For example, one may measure a control in duplicate for more than 20 runs, in which case 20 observations are present with respect to both components. One may here notice that the dispersion of the means (x_m) of the duplicates is given as:

$$\sigma_{xm}^2 = \sigma_{\text{Within-run}}^2/2 + \sigma_{\text{Between-run}}^2$$

From the 20 sets of duplicates, we may derive the within-run SD using the shortcut formula:

$$SD_{\text{Within-run}}^2 = \sum d_i^2/(2 \times 20)$$

where d_i refers to the difference between the ith set of duplicates. When estimating standard deviations, the concept degrees of freedom (df) is used. In a simple situation, the number of degrees of freedom equals $N - 1$. For N duplicates, the number of degrees of freedom is $N(2 - 1) = N$. Thus both variance components are derived in this way. The advantage of this approach is that the within-run estimate is based on several runs, so that an average estimate is obtained rather than only an estimate for one particular run, if all 20 observations had been obtained in the same run. The described approach is a simple example of a *variance component analysis.* The principle can be extended to more components of variation. For example, in the NCCLS EP5-A guideline a procedure is outlined based on the assumption of two analytical runs per day, in which case within-run, between-run, and between-day components of variance are estimated by a *nested* component of variance analysis approach.[76]

There is nothing definitive about the selected number of 20. Quite generally, the estimate of the imprecision improves the more observations that are available. Exact confidence limits for the standard deviation can be derived from the χ^2 distribution. Estimates of the variance, SD^2, are distributed according to the χ^2-distribution (tabulated in most statistics textbooks): $(N-1)SD^2/\sigma^2 \sim \chi^2_{(N-1)}$, where $(N-1)$ is the degrees of freedom.[97] Then the two-sided 95% confidence interval (CI) (95% CI) is derived from the relation:

$\Pr(\chi^2_{97.5\%(N-1)} < (N-1)SD^2/\sigma^2 < \chi^2_{2.5\%(N-1)}) = 0.95$

which yields the 95% CI expression:

$$SD \times \left((N-1)/\chi^2_{2.5\%(N-1)}\right)^{0.5} < \sigma < SD \times \left((N-1)/\chi^2_{97.5\%(N-1)}\right)^{0.5}$$

Example

Suppose we have estimated the imprecision to an SD of 5.0 on the basis of $N = 20$ observations. From a table of the χ^2-distribution, we get the 2.5 and 97.5 percentiles:

$$\chi^2_{2.5\%(19)} = 32.9 \text{ and } \chi^2_{97.5\%(19)} = 8.91$$

where 19 in the parenthesis refers to the number of degrees of freedom. Substituting in the equation, we get:

$$5.0 \times (19/32.9)^{0.5} < \sigma < 5.0 \times (19/8.91)^{0.5}$$

or $3.8 < \sigma < 7.3$.

For reasonable values of N, approximate limits can be derived from the normal approximation[45] of the distribution of the SD being based on the expression of the standard error of σ equal to $[\sigma^2/(2(N-1))]^{0.5}$. Using the normal approximation, the interval equals $5 \pm t_{19}[5^2/(2(20-1))]^{0.5}$, which corresponds to $5 \pm 2.093 \times 0.81 = 3.30 - 6.7$. Thus at the sample size of 20, the approximation is not so good because of the asymmetric distribution of the SD. For a sample size of 50, the approximate interval can be calculated to 4.0 to 6.0, which is a somewhat better approximation of the exact interval of 4.2 to 6.25. Quite generally, it is observed that the uncertainty of the estimated SD is considerable at moderate sample sizes. In Table 14-3 factors corresponding to the 95% CI are given as a function of sample size for simple SD estimation according to the χ^2-distribution. These factors provide guidance on the validity of estimated SDs for

TABLE 14-3 Factors Corresponding to 95% CI Limits for an SD. The number of degrees of freedom is N − 1.

	95% CI	
N	**Lower**	**Upper**
20	0.760	1.460
30	0.797	1.346
40	0.819	1.283
50	0.835	1.243
60	0.848	1.217
70	0.857	1.198
80	0.865	1.183
90	0.872	1.171
100	0.878	1.161
150	0.898	1.128
200	0.911	1.109
250	0.919	1.096
300	0.926	1.087

precision. For individual variance components, the relations are more complicated.

Precision Profile

Precision often depends on the concentration of analyte being considered. A presentation of the precision as a function of analyte concentration is the precision profile, which is usually plotted in terms of the SD or the CV as a function of analyte concentration (Figure 14-3, *A-C*). Some typical examples may be considered. First, the SD may be constant (i.e., independent of the concentration), as it often is for analytes with a limited range of values (e.g., electrolytes). When the SD is constant, the CV varies inversely with the concentration (i.e., it is high in the lower part of the range and low in the high range). For analytes with extended ranges (e.g., hormones), the SD frequently increases as the analyte concentration increases. If a proportional relationship exists, the CV is constant. This may often apply approximately over a large part of the analytical measurement range. Actually, this relationship is anticipated for measurement error arising because of imprecise volume dispensing. Often a more complex relationship exists. Not infrequently, the SD is relatively constant in the low range so that the CV increases in the area approaching the detection limit. At intermediate concentrations, the CV may be relatively constant and perhaps decline somewhat at increasing concentrations. A square root relationship may model the relationship in some situations as an intermediate form of relation between the constant and the proportional case. A constant SD in the low range can be modeled by truncating the assumed proportional or square root relationship at higher concentrations. The relationship between the SD and the concentration is of importance when considering the method specifications

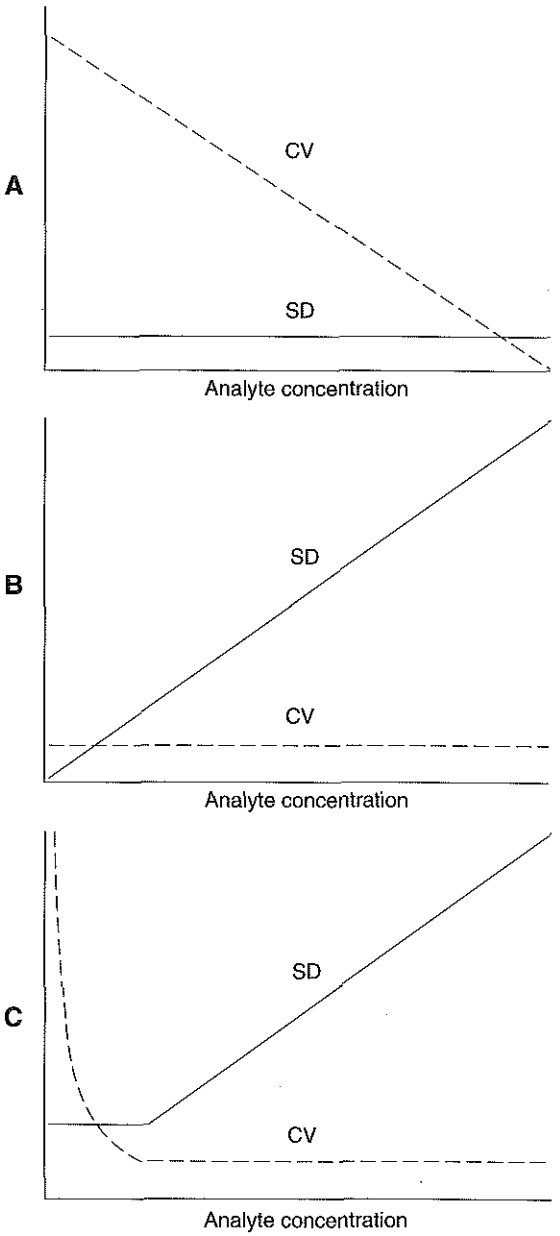

Figure 14-3 Relations between analyte concentration and SD/CV. **A,** The SD is constant so that the CV varies inversely with the analyte concentration. **B,** The CV is constant because of a proportional relationship between concentration and SD. **C,** Illustrates a mixed situation with constant SD in the low range and a proportional relationship in the rest of the analytical measurement range.

over the analytical measurement range, and in the context of selecting appropriate statistical methods for method comparison (e.g., whether a difference or relative difference plot should be applied or whether a simple or a weighted regression analysis procedure should be used) (see the sections entitled "Relative Distribution of Differences Plot" and "Regression Analysis" later in this chapter).

Linearity

Linearity refers to the relationship between measured and expected values over the analytical measurement range. Linearity may be considered in relation to actual or relative analyte concentrations. In the latter case, a dilution series of a sample may be studied. This is often carried out for immunoassays, in which case it is investigated whether the measured concentration declines as expected according to the dilution factor. Dilution is usually carried out with the appropriate sample matrix (e.g., human serum [individual or pooled serum]).

The evaluation of linearity may be carried out in various ways. A simple, but subjective, approach is to visually assess whether the relationship between measured and expected concentration is linear or not. A more formal evaluation may be carried out on the basis of statistical tests. Various principles may be applied here. When repeated measurements are available at each concentration, the random variation between measurements and the variation around an estimated regression line may be evaluated statistically (by an *F*-test).[31] This approach has been criticized because it only relates the magnitudes of random and systematic error without taking the absolute deviations from linearity into account. For example, if the random variation among the measurements is large, a given deviation from linearity may not be declared statistically significant. On the other hand, if the random measurement variation is small, even a very small deviation from linearity that may be clinically unimportant is declared significant. When significant nonlinearity is found, it may be useful to explore nonlinear alternatives to the linear regression line (i.e., polynomials of higher degrees).[24,51]

Another commonly applied approach for detecting nonlinearity is to assess the residuals of an estimated regression line and test for whether positive and negative deviations are randomly distributed. This can be carried out by a runs test[20] (see regression analysis section). An additional consideration for evaluating dilution curves that should be considered is whether an estimated regression line passes through zero or not. Furthermore, testing for linearity is related to assessment of trueness over the analytical measurement range. The presence of linearity is a prerequisite for a high degree of trueness. A NCCLS guideline suggests procedure(s) for assessment of linearity.[79]

Analytical Measurement Range

The analytical measurement range (measuring interval, reportable range) is the analyte concentration range over which the measurements are within the declared tolerances for imprecision and bias of the method.[21] In practice, the upper limit is often set by the linearity limit of the instrument response and the lower limit corresponds to the lower limit of quantitation (LoQ—see below). Usually, it is presumed that the specifications of the method apply throughout the analytical measurement range. However, there may also be situations in which different specifications are applied to various segments of the analytical measurement range. One should also be aware of whether the SD or the CV is specified within certain limits over the analytical measurement range (see Precision Profile, p. 358).

Limit of Detection

The limit of detection (LoD) is medically important for many analytes, especially hormones. The first generation hormone assay frequently has a high LoD, rendering the low results medically useless. Thyroid stimulating hormone (TSH) is a good example. As the assay methods improved, lowering the LoD, low TSH results could be distinguished from the lower limit of the reference interval, making the test useful for the diagnosis of hyperthyroidism.

Concepts

Conventionally the limit of detection often has been defined as the lowest value that significantly exceeds the measurements of a blank sample. Thus the limit has been estimated on the basis of repeated measurements of a blank sample and reported as the mean plus 2 or 3 SDs of the blank measurements. Some problems exist with this conventional approach, and the ISO has recently recommended a formal procedure for estimation of the LoD that is more complicated.[38,41] Therefore the LoD concept is treated in depth in the present exposition to introduce the suggested concepts. First, the distribution of blank values is often asymmetric, making the application of parametric statistics inappropriate (Figure 14-4, *A*). Second, repeated measurements of a sample with a true concentration exactly equal to the limit of statistical significance for blank measurements will yield a distribution with 50% of values below and 50% exceeding the limit because of random measurement error (Figure 14-4, *A*). Only if the true concentration of the sample is higher than the significance limit can one be sure that a measured value will exceed the limit with a probability higher than 50% (Figure 14-4, *B*). In a statistical sense, one should take into account not only the Type I error (the significance test) but also the Type II error, the error of not detecting the presence of analyte that indeed is present.

Given an asymmetric distribution of blank values and applying a significance level (alpha) of 5% (Figure 14-4, *A*), the most straightforward procedure for estimation of the significance limit is to apply a nonparametric principle based on the ordered values for estimation of the 95th percentile. Having ranked N_B values according to size, the 95 percentile may be estimated as the value of the $(N(95/100) + 0.5)$ ordered observation.[15,70,71] In case of a noninteger value, interpolation is carried out between neighbor values (see example). The limiting percentile (Perc) of the blank distribution, which cuts off the percentage α in the upper tail of the distribution, will in the following be called the limit of blank (LoB)

$$\text{LoB} = \text{Perc}_{100-\alpha}$$

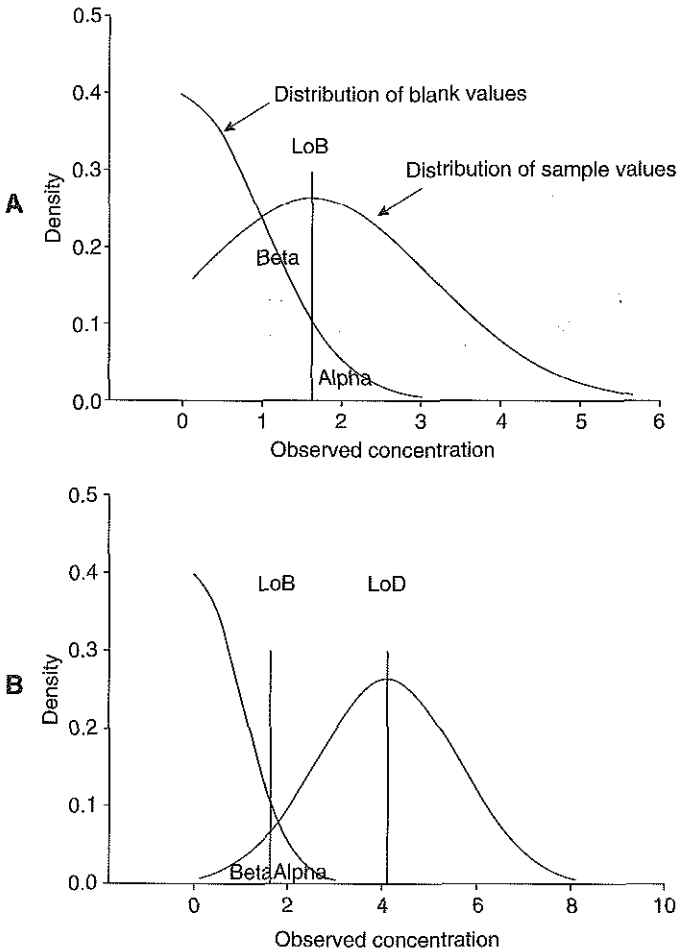

Figure 14-4 Outline of the distribution of blank values, which is truncated at zero, and the distribution of sample values. **A,** When the true sample concentration equals LoB, 50% of the measurements exceed LoB. **B,** At a true sample concentration equal to LoD, (100% – β) (here 95%) of the sample measurements exceed LoB.

To address the Type II error level, one has to consider the minimum sample concentration that provides measured concentration values exceeding LoB with a specified probability. If the Type II error level β is set to 5%, 95% of the measurements should exceed LoB (Figure 14-4, *B*). Usually the sample distribution is Gaussian, and in this case the 5th percentile of the distribution can be estimated from the mean and standard deviation as:

$$x_{mS} - 1.65\,SD_S$$

where x_{mS} and SD_S are the mean and standard deviation of the sample measurements, respectively. Overall, we have:

$$LoD = LoB + 1.65\,SD_S$$

In case the sample distribution is not normal, the 5 percentile of the sample distribution can be estimated nonparametrically in the same way as the LoB. However, parametric estimation is more efficient and should be used when possible.

It is important to realize the exact meaning of the LoD. The LoD expresses a *capability* of the method and should not be used for direct comparison with actually measured sample values. These should be related to the LoB.

Characteristics of Blank and Sample

The blank sample(s) should be as similar as possible to the natural patient samples (e.g., for a drug assay it might be a serum or plasma sample free of drug and not just a buffer solution). To ensure that the measurements are representative, compilation of measurements on a number of blank samples might be preferable. Thus instead of only repeatedly measuring one particular serum sample, a set of 5 to 10 or more blank serum samples would be preferable, because matrix differences exist from sample to sample. For endogenous compounds, it might be samples stripped by the component (e.g., by precipitation using an antibody), by enzymatic degradation, or by adsorption to charcoal. In relation to hormones, blank samples may in some cases be provided from diseased subjects or subjects with suppressed concentrations caused by pharmacological treatment. Concerning tumor markers, samples from nondiseased subjects may be appropriate.

With regard to the sample(s) with low analyte concentration, one may preferably spike a set of serum samples from various patients with the analyte (e.g., a drug), rather than just one serum sample or a serum pool. For endogenous compounds, ideally a set of patient samples with concentrations in the low range might be used. A pooled SD_S estimate can then be derived from repeated measurements of the set of samples (e.g., 10 measurements of each of 10 samples [see the example presented later in this chapter]). Measurements on different days should be carried out, so that SD_S reflects the total analytical variation.

Reporting of Results

In a laboratory, the LoB may be used to decide whether to report patients' results as "detected" or "not detected." Not detected (i.e., a result below LoB) means that the *true* concentration is less than the LoD with 100 – β percent assurance where β is the Type II error level, which often is set to 5%. Thus a result less than LoB should be reported as "less than LoD" and not as "less than LoB" or "zero." A result exceeding LoB (i.e., "detected") means that the true concentration exceeds *zero* with 100 – α percent assurance (where α is the Type I error level), and the reporting could be "greater than zero" or "detected." Results at or exceeding the LoQ (see below) are reported as quantitative results.

A modification of the above-mentioned principles for reporting of results might be considered in case the results are going to be used in scientific studies. Here, unbiased results for groups of subjects being investigated are obtained by reporting the actual measured concentrations irrespective of whether the values are below or above the LoB threshold. Otherwise, biased results may be obtained for the groups.

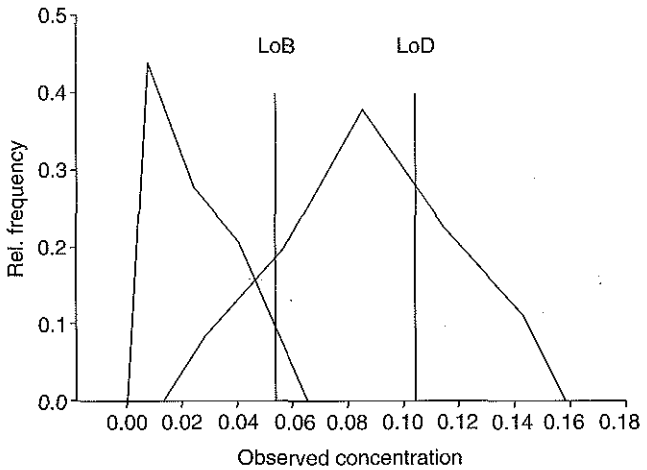

Figure 14-5 Recorded distributions of 100 blank and 100 sample values for the hypothetical hormone example. The estimated LoB (= 95th percentile of the distribution of blank values) and the estimated LoD are indicated. SD_S was derived from the distribution of sample values (actually as a pooled estimate of sets of 10 measurements that are here merged together).

An Example of Estimating the LoD of an Assay

We consider here a hypothetical hormone assay, for which the manufacturer or a research laboratory wants to estimate the LoD. The default values $\alpha = \beta = 5\%$ are used. It is supposed that the manufacturer has 10 samples available from patients lacking the hormone because of disease or pharmacological suppression. Ten measurements of each blank sample are performed on 10 different days to ensure that the total assay variation is reflected. Only nonnegative values are provided by the assay, and the distribution of the 100 blank measurements is skew (Figure 14-5). Thus LoB is estimated nonparametrically as the 95th percentile of the measurement distribution. The 95th percentile corresponds to the 95.5 ordered observation (= 100 × (95/100) + 0.5). The 95 and 96 observations have the values 0.0539 and 0.0548 U/L, respectively. Linear interpolation between the 95 and 96 observations yields an LoB estimate of 0.0544 U/L (= 0.0539 + 0.5 × (0.0548 − 0.0539)).

Samples with low concentrations are obtained from patients. We suppose here that one sample is obtained from each of 10 patients, and that each sample is assayed 10 times (Figure 14-5). A pooled estimate of the SD_S was computed (in this case the square root of the average of the variances—a more general computation procedure is available on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/). An estimate of the LoD is then obtained

$$\text{LoD} = \text{LoB} + 1.65\,SD_S = 0.0544 + 1.65 \times 0.0299 = 0.104\,\text{U/L}$$

This is a point estimate, and the real LoD may be slightly lower or higher. It is possible to derive a CI as described by Linnet and Kondratovich.[71]

Analytical Sensitivity

The detection limit of a method should not be confused with the so-called analytical sensitivity. Analytical sensitivity is the ability of an analytical method to assess small variations of the concentration of analyte.[14] This is often expressed as the slope of the calibration curve.[21] However, in addition to the slope of the calibration function, the random variation of the calibration function should also be taken into account. In point of fact, the analytical sensitivity depends on the ratio between the SD of the calibration function and the slope. As mentioned previously, the smaller the random variation of the instrument response and the steeper the slope, the higher is the ability to distinguish small differences of analyte concentrations. In reality, analytical sensitivity depends on the precision of the method. Historically the meaning of the term analytical sensitivity has been the subject of much discussion.

Limit of Quantitation

The relative uncertainty of measurements at or just exceeding the LoD may be large, and often a quantitative result is not reported. The lower limit for reporting quantitative results, the limit of quantitation (LoQ), relates to the total error being considered acceptable for an assay. From a precision profile for the assay and an evaluation of the bias in the low range, LoQ may be determined in relation to specifications of the method. For example, a laboratory may specify that the total error (e.g., expressed here as Bias + 2 SD) of an assay is lower than 45% (corresponding to a bias of 15% and a CV of 15%) of the measurement concentration.[14,108] In this case, the LoQ is the lowest assay value at which this specification is fulfilled. LoQ constitutes the lowest limit of the reportable range for quantitative results of an assay.

Analytical Specificity and Interference

The analytical specificity is the ability of an assay procedure to determine specifically the concentration of the target analyte in the presence of potentially interfering substances or factors in the sample matrix (e.g., hyperlipemia, hemolysis, bilirubin, anticoagulants, antibodies, and degradation products). For example, in the context of a drug assay, specificity is of relevance in relation to drug metabolites. The interference from hyperlipemia, hemolysis, and bilirubin is generally concentration dependent, and can be quantitated as a function of the concentration of interfering compound.[29] A detailed protocol for evaluation of interference has been published by NCCLS.[80]

In relation to immunoassays, interference from proteins (usually antibodies) should be recognized. Ismail et al[44] found in a survey comprising more than 5000 TSH results that interference occurred in 0.5% of the samples, leading to incorrect results that in a majority of the cases could have changed the treatment. Rotmensch and Cole[94] described 12 patients in whom a diagnosis of postgestational choriocarcinoma was made based on false-positive test results for

human chorionic gonadotropin (hCG). Most of these patients were subjected to unnecessary surgery or chemotherapy. In each case, the false-positive result traced to the presence of heterophilic antibodies that interfered with the immunoassay for hCG. Marks[74] found that almost 10% of immunoassay results from patients with autoimmune disease were erroneous. In many cases, addition of heterophilic antibody blocking reagent or the study of dilution curves or both may help clarify suspected false-positive immunoassay results. Such limitations in the results of immunoassays should be directly communicated to clinicians.

ANALYTICAL GOALS

Setting goals for analytical quality can be based on various principles. A hierarchy has been suggested on the basis of a consensus conference on the subject[86] (Table 14-4). The top level of the hierarchy specifies goals on the basis of the clinical outcome in specific clinical settings, which is a logical principle. For example, one may consider the impact of analytical quality on the error rates of diagnostic or risk classifications.[47,84] A supplementary approach is to study the impact of imprecision and bias on clinical outcome on the basis of a simulation model as described by Boyd and Bruns.[8] For a given analyte, a series of specific clinical settings may then be evaluated, and in principle, the most demanding specification then becomes the goal, at least for a general laboratory serving various clinical applications.

Analytical goals related to biological variation have attracted considerable interest. Originally, focus was on imprecision, and Cotlove et al[13] suggested that the analytical SD (σ_A) should be less than half the intraindividual biological variation, $\sigma_{Within\text{-}B}$. The rationale for this relation is the principle of adding variances. If a subject is undergoing monitoring of an analyte, the random variation from measurement to measurement consists of both analytical and biological components of variation. The total SD for the random variation during monitoring then is determined by the relation

$$\sigma_T^2 = \sigma_{Within\text{-}B}^2 + \sigma_A^2$$

where the biological component includes the preanalytical variation. If σ_A is equal to or less than half the $\sigma_{Within\text{-}B}$ value, σ_T only exceeds $\sigma_{Within\text{-}B}$ by less than 12%. Thus if this relation holds true, analytical imprecision only adds limited random noise in a monitoring situation, and the relationship may be called a *desirable* relation. Alternatively, Fraser et al[27] considered grading of the relationship with additional specifications corresponding to an *optimum* relation ($\sigma_A = 0.25\ \sigma_{Within\text{-}B}$) yielding only 3% additional noise and a *minimum* relation corresponding to 25% additional variation ($\sigma_A = 0.75\ \sigma_{Within\text{-}B}$).[27,28]

In addition to imprecision, goals for bias should also be considered. Gowans et al[30] related the allowable bias to the width of the reference interval, which is determined by the combined within- and between-subject biological variation in addition to the analytical variation. On the basis of considerations concerning the included percentage in an interval in the presence of analytical bias, it was suggested that:

$$\text{Bias} < 0.25\left(\sigma_{Within\text{-}B}^2 + \sigma_{Between\text{-}B}^2\right)^{0.5}$$

where $\sigma_{Between\text{-}B}$ is the between-subject biological standard deviation component.

Thus the bias should *desirably* be less than a fourth of the combined biological standard deviation. One may further extend the suggested relationships to comprise an optimum relation corresponding to a factor 0.125 and a minimum relation with a factor 0.375. Given a normal distribution of reference values, the desirable relationship corresponds to maximum deviations for proportions outside the interval from the expected 2.5% at each side to 1.4% and 4.4%. This gives an overall deviation of 0.8% from the expected total of 5%, corresponding to a relative deviation of 16%, which may be considered acceptable.[28]

Other widely used principles are to relate goals to limits set by regulatory bodies (e.g., Clinical Laboratory Improvements Amendments [CLIA])[104] or professional bodies (e.g., the bias goal of 3% for serum cholesterol [originally 5%]) set by the National Cholesterol Education Program.[75] Table 14-5 provides an overview of analytical goals for important analytes. The goals are given in concentration units using decision levels or critical concentrations (x_c). The decision concentrations are limits of reference or therapeutic intervals or originate from Barnett.[3] Burnett and Westgard[9] have suggested that the analytical CV for a method should not exceed one fourth of CLIA limits so as to include the possibility of

unstable method performance and the use of cost-effective quality control procedures. Ricos et al[91] have published a comprehensive listing of data on biological variation with a database that is available on the internet (Ricos et al, Biological Variation Database, www.westgard.com/guest17.htm, accessed August, 2003).

Qualitative Methods

Qualitative methods, which currently are gaining increasing use in the form of point-of-care testing (POCT), are designed to distinguish between results below or above a predefined cut-off value. Notice that the cut-off point should not be confused with the detection limit. These tests are primarily assessed on the basis of their ability to correctly classify results in relation to the cut-off value.

Performance Measures

The probability of classifying a result as positive (exceeding the cutoff), in case the true value indeed exceeds the cutoff, is called the clinical sensitivity. Classifying a result as negative (below the cutoff), in case the true value indeed is below

the cutoff, is termed the clinical specificity. Determination of clinical sensitivity and specificity is based upon comparison of the test results with a gold standard. The gold standard may be an independent test that measures the same analyte, but it may also be a clinical diagnosis determined by definitive clinical methods (e.g., radiographic testing, follow-up, or outcomes analysis). Determination of these performance measures is covered in Chapter 15. The clinical sensitivity and specificity may be given as a fraction or as a percentage after multiplication by 100. Standard errors of estimates are derived from the binomial distribution.[97] Comparison of the performance of two qualitative tests applied on the same groups of nondiseased and diseased subjects can be performed by McNemar's test.[60]

One approach for determining the recorded performance of a test in terms of clinical sensitivity and specificity is to determine the true concentration of analyte using an independent reference method. The closer the concentration is to the cut-off point, the larger error frequencies are to be expected. Actually the cut-off point is defined in such a way that for samples having a true concentration exactly equal to the cut-off point, 50% of the results will be positive and 50% will be negative.[25] The concentrations above and below the cut-off point at which repeated results are 95% positive or 95% negative, respectively, have been called the "95% interval" for the cut-off point for that method[25] (notice that this is not a CI; Figure 14-6). Thus in an evaluation of a qualitative test, it is important to specify the composition of the samples in detail. Recently a NCCLS guideline on the topic has suggested a protocol for evaluation.[78] Briefly, it is recommended to prepare samples with a concentration equal to the cut-off point and with concentrations 20% below and above the point. Twenty replicate measurements are then carried out at each concentration, and the percentages of positive and neg-

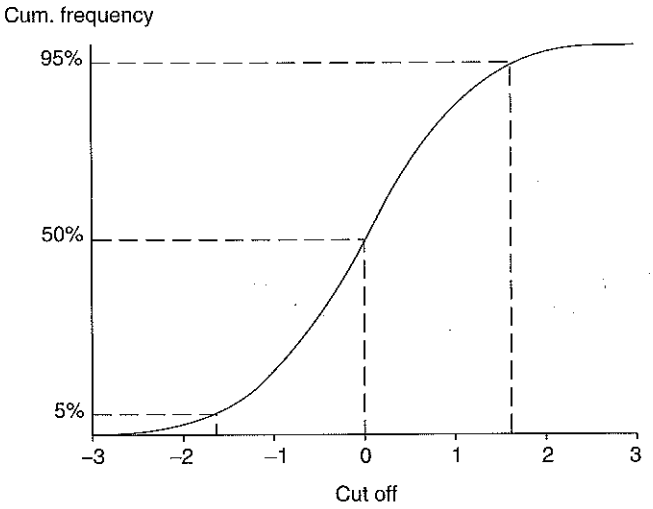

Figure 14-6 Cumulative frequency distribution of positive results. The *x*-axis indicates concentrations standardized to zero at the cut-off point (50% positive results) with unit SD.

ative results are recorded. On the basis of these measurements, it can be judged whether the "95% interval" for the cut-off point is within or outside this interval. In relation to the suggested procedure, one should be aware of the limitations associated with repeated measurements of pools. Measurements of individual patient samples with the specified concentrations are preferable to get a true impression of possible matrix effects.

Agreement Between Qualitative Tests

As outlined above, if the outcome of a qualitative test can be related to a true analyte concentration or a definitive clinical diagnosis, it is relatively straightforward to express the performance in terms of clinical specificity and sensitivity. In the absence of a definitive reference or "gold standard," one should be cautious with regard to judgments on performance. In this situation, it is primarily *agreement* with another test that can be assessed. When considering replacement of an old or expensive routine method with a new or cheap method, it is of interest to know whether similar test results are likely to be obtained. If both methods are imperfect, however, it is not possible to judge which test has the best performance, unless additional testing by a reference procedure is carried out.

In a comparison study, the same individuals are tested by both methods to prevent bias associated with selection of patients. Basically the outcome of the comparison study should be presented in the form of a 2 × 2 table, from which various measures of agreement may be derived (Table 14-6). An obvious measure of agreement is the overall fraction or percentage of the subjects tested that have the same test result (i.e., both results negative or positive)

$$\text{Overall percent agreement} = (a + d)/(a + b + c + d) \times 100\%$$

TABLE 14-6 2 × 2 Table for Assessing Agreement between Two Qualitative Tests

		Test 1	
		+	−
Test 2	+	a	b
	−	c	d
	Total	$a + c$	$b + d$

If the agreement differs with respect to diseased and healthy individuals, the overall percent agreement measure becomes dependent on the disease prevalence in the studied group of subjects. This is a common situation, and accordingly it may be desirable to separate this overall agreement measure into agreement concerning negative and positive results:

$$\text{Percent agreement given test 1 positive: } a/(a + c) \times 100\%$$

$$\text{Percent agreement given test 1 negative: } b/(b + d) \times 100\%$$

For example, if there is a high agreement with regard to positive results, the overall agreement will be high when the fraction of diseased subjects is high; but in a screening situation with very low disease prevalence, the overall agreement will mainly depend on agreement with regard to negative results. Standard errors of the estimates can be derived from the binomial distribution.[62,97]

A problem with the above-mentioned simple agreement measures is that they do not take agreement by chance into account. Given independence, the expected proportions observed in the fields of the 2 × 2 table are obtained by multiplication of the fractions of negative and positive results for each test. Concerning agreement, it is the excess agreement beyond chance that is of interest. More sophisticated measures have been introduced to account for this aspect. The most well-known measure is kappa, which is defined generally as the ratio of observed excess agreement beyond chance to the maximum possible excess agreement beyond chance.[26] We have:

$$\text{Kappa} = (I_o - I_e)/(1 - I_e)$$

where I_o is the observed index of agreement and I_e is the expected agreement from chance. Given complete agreement, kappa equals +1. If observed agreement is greater than or equal to chance agreement, kappa is larger than or equal to zero. Observed agreement worse than chance yields a negative kappa value.

Example

Table 14-7 shows a hypothetical example of observed numbers in a 2 × 2 table. The proportion of positive results for Test 1 is $75/(75 + 60) = 0.555$ and $80/(80 + 55) = 0.593$ for Test 2. Thus by chance we expect the ++ pattern in $0.555 \times 0.593 \times 135 = 44.44$ cases. Analogously, the −− pattern is

TABLE 14-7 2 × 2 Table with Example of Agreement Data for Two Qualitative Tests

		Test 1		
		+	−	**Total**
Test 2	+	60	20	80
	−	15	40	55
Total		75	60	135

expected in $(1 - 0.555) \times (1 - 0.593) \times 135 = 24.45$ cases. The expected overall agreement by chance I_e is $(44.44 + 24.45)/135 = 0.51$. The observed overall agreement is $I_o = (60 + 40)/135 = 0.74$. Thus we have:

$$\text{Kappa} = (0.74 - 0.51)/(1 - 0.51) = 0.47$$

Kappa values greater than 0.75 are generally taken to indicate excellent agreement beyond chance, values from 0.40 to 0.75 are regarded as fair-to-good agreement beyond chance, and finally, values below 0.40 represent poor agreement beyond chance. A standard error for the kappa estimate can be computed.[26] Kappa is related to the intraclass correlation coefficient, which is a widely used measure of interrater reliability for quantitative measurements.[26] The considered agreement measures, percent agreement, and kappa can also be applied to assess the reproducibility of a qualitative test when the test is applied twice in a given context.

Various methodological problems are encountered in studies on qualitative tests. An obvious mistake is to let the result of the test being evaluated contribute to the diagnostic classification of the subjects being tested (circular argument). Another problem is partial as opposed to complete verification. When a new test is compared with an existing, imperfect test a partial verification is sometimes undertaken, in which only discrepant results are subjected to further testing by a perfect test procedure. On this basis, sensitivity and specificity are reported for the new test. This procedure (called discrepant resolution) leads to biased estimates and should not be accepted.[72] The problem is that for cases with agreement, both the existing (imperfect test) and the new test may be wrong. Thus only a measure of agreement should be reported, not specificity and sensitivity values. In the biostatistical literature, various procedures have been suggested to correct for bias caused by imperfect reference tests, but unrealistic assumptions concerning independence of test results are usually put forward.

METHOD COMPARISON

Comparison of measurements by two methods is a frequent task in the laboratory. Preferably, parallel measurements of a set of patient samples should be undertaken. To prevent artificial matrix-induced differences, fresh patient samples are the optimal material. A nearly-even distribution of values over the analytical measurement range is also preferable. In an ordinary laboratory, comparison of two field methods will be the most frequently occurring situation. Less commonly, comparison of a field method with a reference method is undertaken. When comparing two field methods, the focus is on the observed differences. In this situation, it is not possible to establish that one set of the measurements is the correct one and then consider the deviation of the other set of measurements from the presumed correct concentrations. Rather, the question is whether the new method can replace the existing one without a general change in measurement level. To address this question, the dispersion of observed differences between the paired measurements by the methods may be evaluated. To carry out a formal, objective analysis of the data, a statistical procedure with graphics display should be applied. Various approaches exist: (1) a frequency plot or histogram of the distribution of differences with measures of the central tendency and the dispersion (distribution of differences [DoD] plot); (2) a difference (bias) plot, which shows the differences as a function of the average concentration of the measurements (Bland-Altman plot); and (3) a regression analysis. In the following, a general error model is presented, and some typical measurement relationships are considered. Each of the mentioned statistical approaches will be presented in detail with a discussion of their advantages and disadvantages.

BASIC ERROR MODEL

The occurrence of measurement errors is related to the performance characteristics of the assay, primarily bias, imprecision, and specificity as defined above. The overall influence of these factors may be incorporated in an error model.

True Value and Target Value

Taking into account that an analytical method measures analyte concentrations with some uncertainty, one has to distinguish between the measured value (x_i) and the target value ($X_{\text{Target}i}$) of a sample subjected to analysis by a given method. The latter is the average result we would obtain, if the given sample was measured an infinite number of times. The measured value is likely to deviate from the target value by some small "random" amount (ε). For a given sample measured by an analytical method, we have:

$$x_i = X_{\text{Target}i} + \varepsilon_i$$

If the method is a reference method without bias and nonspecificity, the target value equals the true value, i.e.,

$$X_{\text{Target}i} = X_{\text{True}i}$$

Given a field method, some bias or nonspecificity may be present, and the target and true values are likely to differ somewhat. For example, if we measure creatinine with a chromogenic method, which co-determines some other components with creatinine in serum, we will likely obtain a higher target value than when we use a specific isotope-dilution mass spectrometry (ID-MS) reference method (i.e.,

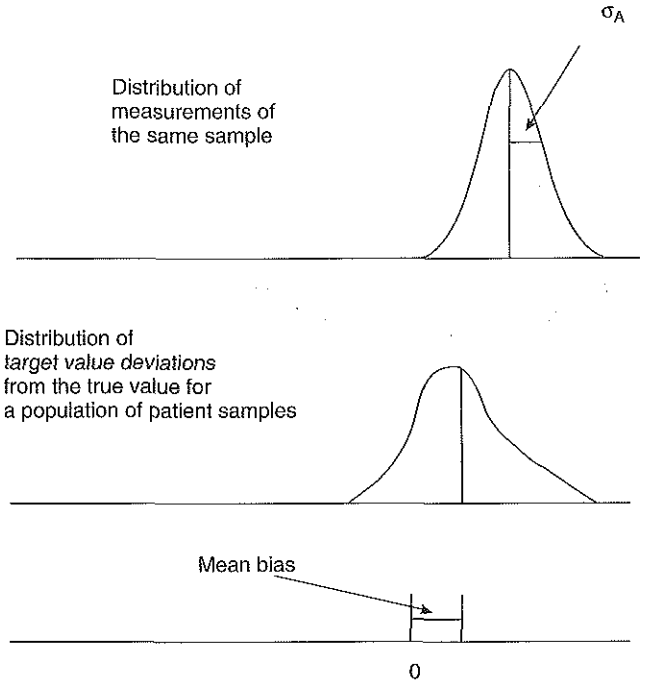

Figure 14-7 Outline of basic error model for measurements by a field method. *Upper part:* The distribution of repeated measurements of the *same* sample, representing a normal distribution around the target value *(vertical line)* of the sample with a dispersion corresponding to the analytical standard deviation, σ_A. *Middle part:* Schematic outline of the dispersion of target value deviations from the respective true values for a population of patient samples. A distribution of an arbitrary form is displayed. The vertical line indicates the mean of the distribution. *Lower part:* The distance from zero to the mean of the target value deviations from the true values represents the mean bias of the method.

the target value of the chromogenic method exceeds the true value determined by repetitive reference method measurements). Thus we have the relation

$$X_{\text{Target}i} = X_{\text{True}i} + \text{Bias}_i$$

Because the amounts of co-determined substances may vary from sample to sample, the bias is likely to differ somewhat from sample to sample. For a representative set of patient samples, we may describe the biases associated with the individual samples by the central tendency (mean or median) and the dispersion (Figure 14-7). Thus the bias may be split into an average amount: the mean bias, and a random part, random bias.[48,53,55,58] For an individual sample, we have

$$X_{\text{Target}i} = X_{\text{True}i} + \text{Mean-Bias} + \text{Random-Bias}_i$$

For example, the chromogenic creatinine method may on average determine creatinine values 15% too high, which then constitutes the mean bias. For individual samples, the particular bias may be slightly higher or lower than 15% depending on the actual chromogenic content.

Mean Bias and Random Bias

Taking mean bias and random bias into account, we obtain the following expression for an individual measurement of a given sample by a field method

$$x_i = X_{\text{Target}i} + \varepsilon_i = X_{\text{True}i} + \text{Mean-Bias} + \text{Random-Bias}_i + \varepsilon_i$$

For such an individual measurement the total error is the deviation of x_i from the true value, i.e.,

$$\text{Total error of } x_i = \text{Mean-Bias} + \text{Random-Bias}_i + \varepsilon_i$$

Thus the total error is composed of a mean bias, a random matrix-related interference component, and finally a random measurement error element. The latter component can be assessed from repeated measurements of the given sample by the method in question and can be expressed as a standard deviation (i.e., the analytical standard deviation as previously described [either within or between runs]). Estimation of the other elements requires parallel measurements between the method in question and a reference method as outlined in detail later.

The exposition above defines the total error in somewhat broader terms than often is seen. A traditional total error expression is[106]

$$\text{Total error} = \text{Bias} + 2\,\text{SD}_A$$

which often is interpreted as the mean bias plus 2 SD_A. If a one-sided statistical perspective is taken, the expression is modified to Bias + 1.65 SD_A, indicating 5% of results being located outside the limit. If a lower percentage is desired, the multiplication factor is increased accordingly, supposing a normal distribution. Interpreting the bias as being identical with the mean bias may lead to an underestimation of the total error.

When the mean bias is considered, one should distinguish between specific (systematic) sample-related interference (e.g., the influence of hemolysis on a photometric assay) in which a clear concentration dependent effect is present and general nonspecificity of the assay. The former can be handled appropriately, either by systematic corrections or by setting limits for allowed degrees of hemolysis.[29]

Random matrix-related interference may take several forms. It may be a regularly occurring additional random error component, perhaps of the same order of magnitude as the analytical error. In this context, it is natural to quantify the error in the form of an SD or CV. The most straightforward procedure is to carry out a method comparison study based on a set of patient samples, where one of the methods is a reference method as outlined later. Often reference methods are not available, and Lawton et al[58] described a multiple method comparison technique based on principal component analysis to quantify random bias components. Applying at least three field methods, it is possible, given certain assumptions concerning independence with regard to interference, to estimate random bias com-

ponents. Krouwer[53] formally quantified sample-related random effects in a comparison experiment of two cholesterol methods and found that the CV of the sample-related random interference component exceeded the analytical CV. Kringle and Bogovich[48] considered random bias of a Jaffé creatinine method by components of variance analysis and also found random bias to be a pronounced random error component, constituting 80% of the total random error. This relatively high amount should be regarded in light of the limited specificity of the Jaffé creatinine measurement principle.

Another form of random matrix-related interference is more rarely occurring gross errors, which typically are seen in the context of immunoassays and relate to unexpected antibody interactions (see interference section).[44,74,94] Such an error will usually show up as an outlier in method comparison studies. A well-known source is the occurrence of heterophilic antibodies. This is the background for the fact that outliers should be carefully considered and not just discarded from the data analysis procedure. Supplementary studies may help clarify such random matrix-related interferences and may provide specifications for the assay that limit its application in certain contexts (e.g., with regard to samples from certain patient categories).

Mean Bias and Analyte Concentration

When considering mean bias, one should recognize that the mean bias may be a function of the analyte concentration. For example, it may be positive at low concentrations and negative at high concentrations. This may occur in cases in which there is some nonspecificity of the method, yielding values that are generally too high. In the high concentration range, however, nonlinearity in the negative direction may predominate over the positive bias because of nonspecificity. In this case, the recorded mean bias for a set of samples becomes dependent on the distribution of sample values. For an even distribution of sample values over the whole range, the mean bias may be close to zero (see later example concerning the paired *t*-test). For a set of samples with values limited to the lower part of the analytical measurement range, the mean bias may be positive. Finally the recorded mean bias may be negative for sets of samples with only high values.

Blunders or Clerical Errors

Another reason for outliers in method comparison studies and in daily practice is *blunders* or *clerical errors*. In the past, this type of error usually arose in relation to manual transfer of results. Today, this kind of error typically is related to computer errors originating at interfaces between computer systems. Bonini et al[6] concluded on the basis of a literature review that laboratory errors occurred more frequently in the preanalytical or postanalytical phases than in the analytical part. Errors on test order forms or errors related to handling of order forms appear to occur relatively frequently (1% to 5% of recorded cases). In the postanalytical phase, inappropriate interpretation may take place (e.g., in relation to erroneous reference intervals).

Method Comparison Data Model

We here consider our error model in relation to the method comparison situation. For a given sample measured by two analytical methods, 1 and 2, we have

$$x1_i = X1_{\text{Target}i} + \varepsilon 1_i = X_{\text{True}i} + \text{Mean-Bias1} + \text{Random-Bias1}_i + \varepsilon 1_i$$

$$x2_i = X2_{\text{Target}i} + \varepsilon 2_i = X_{\text{True}i} + \text{Mean-Bias2} + \text{Random-Bias2}_i + \varepsilon 2_i$$

From this general model we may study some typical situations. First, comparison of a field method with a reference method will be treated. Secondly the more frequently occurring situation, the comparison of two field methods, is considered.

Comparison of a Field Method With a Reference Method

We may start supposing that method 1 is a reference method. In this case, the bias components per definition disappear, and we have the following situation:

$$x1_i = X1_{\text{Target}i} + \varepsilon 1_i = X_{\text{True}i} + \varepsilon 1_i$$

$$x2_i = X2_{\text{Target}i} + \varepsilon 2_i = X_{\text{True}i} + \text{Mean-Bias2} + \text{Random-Bias2}_i + \varepsilon 2_i$$

The paired differences become

$$(x2_i - x1_i) = \text{Mean-Bias2} + \text{Random-Bias2}_i + (\varepsilon 2_i - \varepsilon 1_i)$$

We thus have an expression consisting of a constant term (the mean bias of method 2) and two random terms. The random bias term is distributed around the mean bias according to an undefined distribution. The second random term is a difference between two random measurement errors that are independent and commonly, normally distributed. Under these assumptions, the differences between the random measurement errors are also random and normally distributed. However, we remind the reader that the standard deviation for analytical methods often depends on the concentration level as mentioned earlier. For analytes with a wide analytical measurement range (e.g., some hormones), both the random matrix-related interferences and the analytical SDs are likely to depend on the measurement concentration, often in a roughly proportional manner. It may then be more useful to evaluate the *relative* differences: $(x2_i - x1_i)/[(x2_i + x1_i)/2]$ and accordingly express mean and random bias, and analytical error as proportions. An alternative is to partition the total analytical measurement range into segments (e.g., three parts), and consider mean bias, random bias and analytical error separately for these segments. The segments may preferably be divided in relation to important decision concentrations (e.g., in relation to reference interval limits and/or treatment decision concentrations).

Comparison of Two Field Methods

In the comparison of two field methods, the paired differences become:

$$(x2_i - x1_i) = (\text{Mean-Bias2} - \text{Mean-Bias1}) + (\text{Random-Bias2}_i - \text{Random-Bias1}_i) + (\varepsilon 2_i - \varepsilon 1_i)$$

The expression again consists of a constant term, the difference between the two mean biases, and two random terms. The first random term is a difference between two random-bias components that may or may not be independent. If the two field methods are based on the same measurement principle, the random bias terms are likely to be correlated. For example, two chromogenic methods for creatinine are likely to be subject to interference from the same chromogenic compounds present in a given serum sample. On the other hand, a chromogenic and an enzymatic creatinine method are subject to different types of interfering compounds, and the random-bias terms may be relatively independent. In the $\varepsilon 2_i - \varepsilon 1_i$ term, the same relationships as described above are likely to apply. One may notice that the general form of the expressed differences is the same in the two situations. Thus the same general statistical principles actually apply. In the following sections, we will consider the distribution of differences under various circumstances and also consider the measurement relations between method 1 and 2 on the basis of regression analysis.

Preliminary Practical Work in Relation to a Method Comparison Study

When preparing a method comparison study, the analytical methods to be studied should be established in the laboratory according to written protocols and stable in routine performance. Reagents are commonly supplied as ready-made analytical kits, perhaps implemented on a dedicated analytical instrument (open or closed system). The technologists performing the study should be trained in the procedures and associated instrumentation. Further, it is important that an internal quality control system is in place to ensure that the methods being compared are running in the in-control state.

Planning a Method Comparison Study

In the planning phase of a method comparison study, several points require attention, including the number of samples necessary, the distribution of analyte concentrations (preferably uniform over the analytical measurement range), and the representativeness of the samples. To address the latter point, samples from relevant patient categories should be included, so that possible interference phenomena can be discovered. Practical aspects related to storage and treatment of samples (container, etc.) and possible artifacts induced by storage (e.g., freezing of samples) and addition of anticoagulants should be considered. Comparison of measurements should preferably be undertaken over several days (e.g., at least 5 days), so that the comparison of methods does not become dependent on the performance of the methods in one particular analytical run. Finally, ethical aspects (e.g., informed consent from patients whose samples will be used) should be considered in relation to existing legislation.

When considering the comparison protocol, various guidelines may be consulted. The NCCLS Evaluation Protocol (EP) guidelines give advice on various aspects. For example, the NCCLS guideline EP-9A2: *Method Comparison and Bias Estimation Using Patient Samples* suggests measurement of 40 samples in duplicate by each method, when a new method is introduced in the laboratory as a substitute for an established one.[81] Additionally, it is proposed that a vendor of an analytical test system should have made a comparison study based on at least 100 samples measured in duplicate by each method. The principle of a more demanding requirement for vendors appears reasonable. This initial validation should be comprehensive to disclose the performance of the assay system in detail. Then the requirement for the ordinary user may be more modest.

Although these general guidelines on sample size are useful, further aspects are important. Statistical power may be considered as a basis for considering the appropriate sample size as presented under regression analysis. Additionally the probability of detecting rarely occurring interferences showing up as outliers should be taken into account when considering the necessary sample size. Finally, in relation to evaluation of automated methods, special consideration should be given to the sample sequence to evaluate drift, carryover, and nonlinearity (e.g., by a multifactorial design).[52]

Distribution of Differences Plot (DoD plot)

From the end-user viewpoint, it is the differences per se that matter. Thus with regard to the outcome of replacing an established field method with a new one that perhaps is cheaper or more practical, it is important to focus on the distribution of differences between paired measurements by the old and the new method. A graphic display with assessment of the central tendency and the dispersion of the differences in the form of an ordinary histogram or frequency polygon plot is useful. The differences may or may not be normally distributed. Because both analytical error components and random matrix-related interferences may contribute to the differences, the distribution may be irregular and outliers may occur. Further, the random dispersion elements may be dependent on analyte concentration. Therefore a nonparametric approach for interpreting the distribution of differences may generally be preferable as a starting point.

Nonparametric Approach

Both the central tendency (median) and extreme percentiles are of interest when using the nonparametric approach to the distribution of differences. Given a traditional 95% level, the 2.5 and 97.5 percentiles are considered. A 99% or more extreme level may also be selected, and the related percentiles

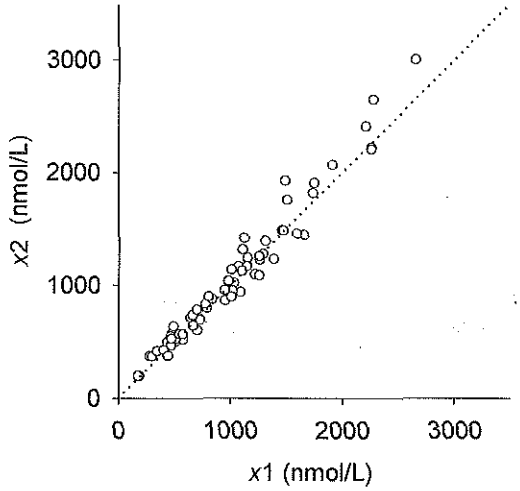

Figure 14-8 A scatter plot of $N = 65$ ($x1$, $x2$) data points for comparison of two drug assays. The dashed line is the line of identity.

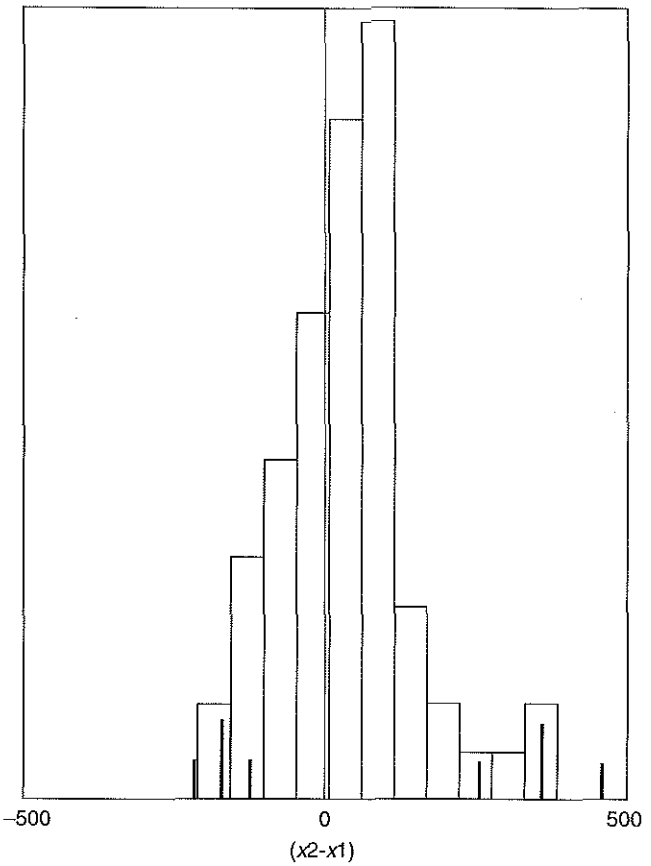

Figure 14-9 DoD plot for comparison of two drug assays: nonparametric analysis. A histogram shows the relative frequency of $N = 65$ differences with demarcated 2.5 and 97.5 percentiles determined nonparametrically. The 90% CIs of the percentiles are shown. These were derived by the bootstrap technique.

(0.5 and 99.5 or more extreme ones) are then applied for description of method differences. Nonparametric estimation of the 2.5 and 97.5 percentiles requires 2.5 times as many observations as the parametric approach to provide the same precision, which implies that sample sizes cannot be too small.[70] Estimating confidence limits of the percentiles can give an indication of their imprecision. The CIs can be estimated from the ordered observations as described in Chapter 16 in the section on nonparametric estimation of the 95% reference interval. Alternatively a bootstrap procedure, available on the book's accompanying Evolve site, can be applied as described.[70] The advantage of the bootstrap procedure is that standard errors can be derived using smaller sample sizes than by the simple nonparametric approach.

A method comparison example from one of the authors' laboratory is considered (KL). Two in-house developed drug assays for serum concentrations of the antipsychotic drug clozapine are compared. The established assay (method 1) is an HPLC method based on manual liquid-liquid extraction. The new method (method 2) is an HPLC method with an automated on-column extraction step. An initial impression of the relation between $x1$ and $x2$ measurements can be obtained from a scatter plot of the 65 measurement sets ($x1$, $x2$) with the identity line outlined (Figure 14-8). The $x1$ and $x2$ values are displayed in Table 14-17, which is available on the book's accompanying Evolve site. The $x1$ measurements range from 177 to 2650 nmol/L, and the range of $x2$ values is from 200 to 3004 nmol/L (i.e., we have a relatively wide analytical measurement range in the present example). A histogram of the differences ($x2 - x1$) is shown in Figure 14-9. Applying a nonparametric data description, we order the observed differences according to size and derive the median difference as the value of the $(0.5N + 0.5)$ ordered observation, here 26 nmol/L. In case the order is a noninteger, interpolation between neighbor-ordered values is carried out. A paired nonparametric test, the Wilcoxon test,[97] showed that the median difference was significantly higher than zero (P less than 0.02). The 2.5 and 97.5 percentiles correspond to the values of the $(0.025N + 0.5)$ and the $(0.975N + 0.5)$ ordered observations, respectively, as displayed in Table 14-8.[15,70] For a sample size of less than 120, it is not possible to derive CIs for the percentiles by the simple nonparametric procedure. Therefore we also applied the bootstrap procedure to estimate nonparametric percentiles with 90% CIs[70] (Table 14-8) (see the book's accompanying Evolve site). The bootstrap procedure, which is based on computerized random resampling of the observations, provides slightly different percentile estimates as shown in the table. In this way, we obtain an estimation of the size of negative and positive differences with uncertainties. In the present example, there is a considerable range of differences, the 2.5 percentile being −169 nmol/L (90% CI: −214 to −123), and the 97.5 percentile being 356 nmol/L (90% CI: 255 to 457). The relatively large differences should be related to the considerable analytical measurement range for the analyte, and an

Outlier test (4 SD)			n.s.
2.5 percentile	−166.00	−169.11	−201.86
97.5 percentile	372.38	355.90	285.86
90% CI for 2.5 percentile		−214.73 to −123.50	−245.24 to −158.47
90% CI for 97.5 percentile		255.03 to 456.77	242.47 to 329.24

evaluation of *relative* differences may in the present example be more relevant (see later in this chapter).

In the presented examples, no evident outliers were present. However, outliers deserve special attention. Unless they are related to obvious method or apparatus malfunction, the discarding of outliers should be considered with caution. Outliers may indicate the presence of large random matrix-related interferences, which may be of major clinical importance (e.g., interference by antibodies or degradation products that only occur rarely). Thus a special investigation of outlying results with reanalysis and exploration of the reasons for the outlying observations should be considered. A statistical evaluation of outliers is available on the book's accompanying Evolve site.

Parametric Approach

If application of a goodness-of-fit test does not disprove that the distribution of differences is normally distributed, a parametric statistical approach may be undertaken. In the presented example, there was a significant deviation from normality as assessed by the Anderson-Darling test[61] (P less than 0.01), and a parametric analysis should in principle not be carried out. However, to demonstrate the procedure, the parametric approach is also carried out (Figure 14-10 and Table 14-8). The mean and standard deviation (SD_{Dif}) of the paired differences ($x2 - x1$) are estimated according to standard procedures. A paired t-test is used to determine whether the mean difference is significantly different from zero or not (P less than 0.01 in this case). The 2.5 and 97.5 percentiles for the differences are estimated as the mean $\pm t_{0.025,(N-1)}$ SD_{Dif}. A standard error for the percentiles (SE_{perc}) may be computed as specified on the book's accompanying Evolve site, and the 90% CI limits are then derived as ± 1.65 SE_{perc} around the

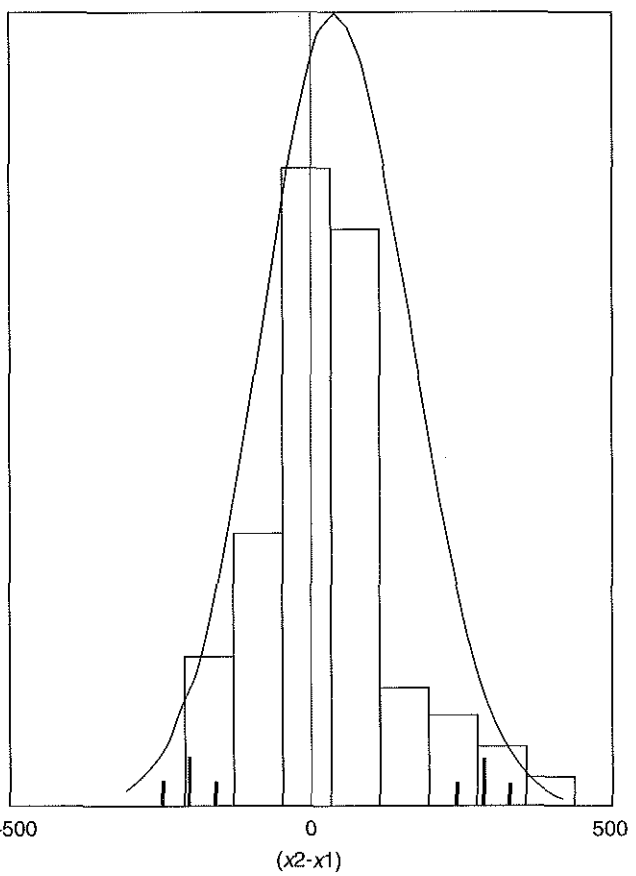

Figure 14-10 DoD plot for comparison of two drug assays: parametric analysis. A histogram shows the relative frequency of $N = 65$ differences with the estimated Gaussian density distribution. Parametrically estimated 2.5 and 97.5 percentiles are shown with 90% CIs.

percentiles (Figure 14-10 and Table 14-8). The parametrically derived 2.5 and 97.5 percentiles (−202 and 286 nmol/L) differ somewhat from the nonparametrically derived percentiles, which in the present context with proven nonnormality may be regarded as the most reliable estimates.

Relative Distribution of Differences Plot (Rel. DoD plot)

In many cases in which there is a wide analytical measurement range (i.e., corresponding to 1 or several decades), the random error components depend on the concentration as previously mentioned. The analytical SDs may be approximately proportional to the concentration over the major part of the analytical measurement range, and this relationship may also apply to the random matrix-related interferences. In the present example, the initial scatter plot of ($x1$, $x2$) values suggests that the random error of the differences increases with the concentration (see Figure 14-8). A formal test for this possible relation is to compute the correlation coefficient between the average concentration and the *absolute* value of the differences. This correlation coefficient, r, is +0.57 (P less than 0.001) and thus confirms the relationship of an increasing scatter with the concentration, which also can be visualized in a scatter plot of the absolute differences against the average concentration (Figure 14-11). A natural next step is then to assess the *relative* differences in relation to the average concentration. The correlation coefficient between the absolute values of the relative differences ($[x2 - x1]/[\{x1 + x2\}/2]$) and the average concentration ($[x1 + x2]/2$) was not significantly different from zero ($r = -0.15$), and a scatter plot also suggests a more homogeneous dispersion (Figure 14-12). In this situation, it is more reasonable to deal with *relative* differences or percentage differences ($[x2 - x1]/[\{x1 + x2\}/2] \times 100\%$). The same nonparametric descriptive measures as used above may be applied for the central tendency and the dispersion (Figure 14-13). The median relative difference amounts to 0.042 or 4.2%, which is significantly

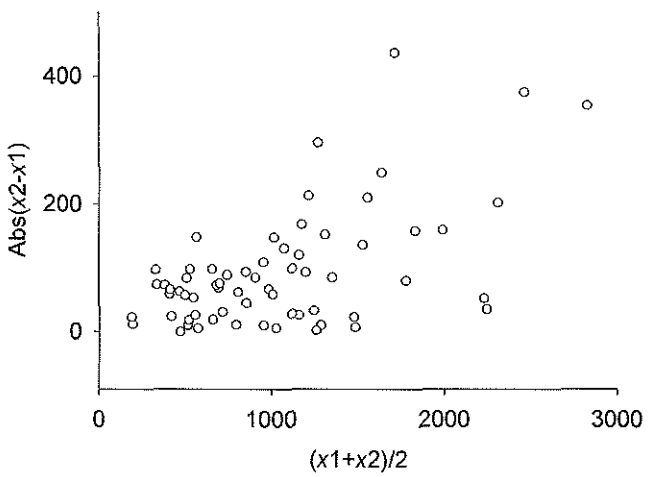

Figure 14-11 Plot of absolute differences (ordinate) against average concentration (abscissa) for the comparison of drug assays example. The scatter increases with the average concentration ($r = +0.57$).

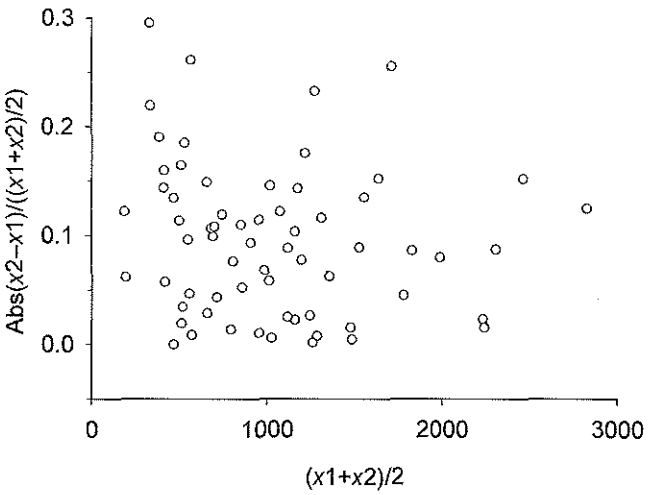

Figure 14-12 Plot of absolute *relative* differences (ordinate) against average concentration (abscissa) for the comparison of drug assays example. The scatter is not significantly correlated with the average concentration ($r = -0.15$, not significant).

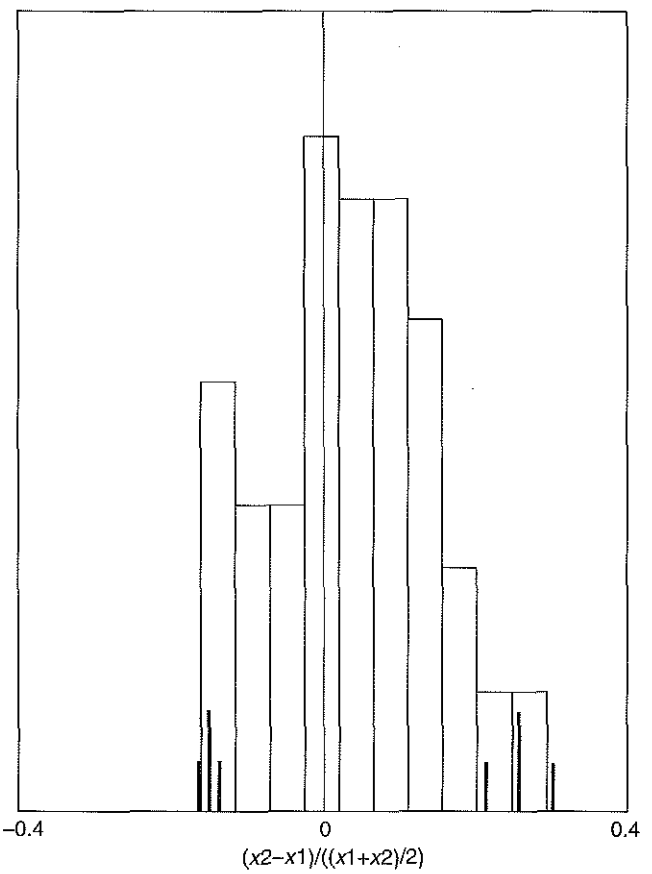

Figure 14-13 Rel. DoD plot for comparison of two drug assays: nonparametric analysis. A histogram shows the relative frequency of relative differences with demarcated 2.5 and 97.5 percentiles determined nonparametrically. The 90% CIs (bootstrap) of the percentiles are shown.

higher than zero (P less than 0.01) (Table 14-9). The 2.5 and 97.5 percentiles are −0.15 and 0.26, respectively. The 90% CIs derived by the bootstrap procedure were −0.16 to −0.14 and 0.21 to 0.30, respectively. Thus from this analysis we may conclude that the 95% interval for percentage differences ranges from about −15% to +26%.

Finally, we may consider a parametric analysis of the relative differences (Figure 14-14 and Table 14-9). A goodness-of-fit test (Anderson-Darling test, P greater than 0.5) showed that the relative differences did not depart significantly from a normal distribution, which in this case supports the parametric approach (Figure 14-15). The parametric 2.5 and 97.5

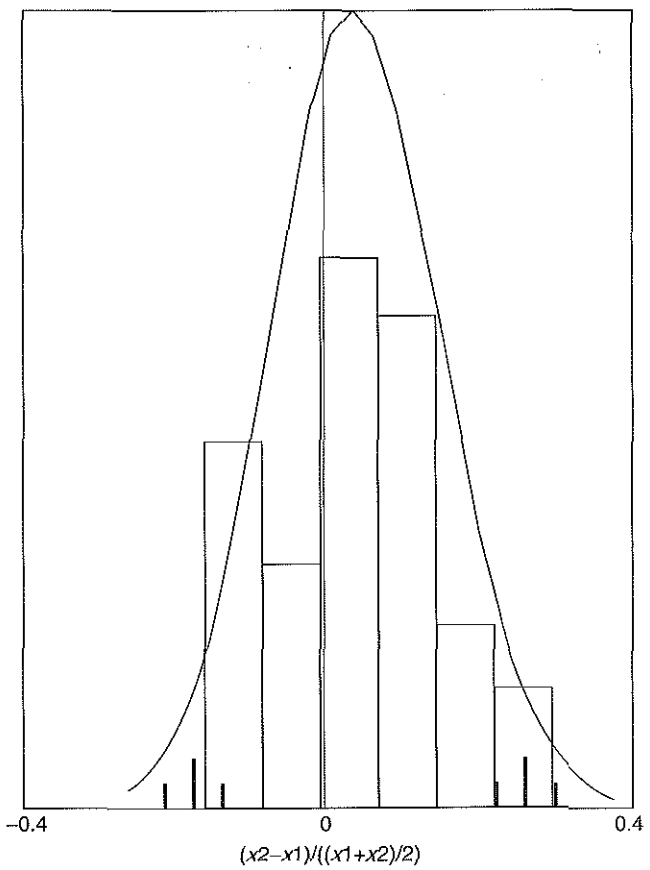

Figure 14-14 Distribution of *relative* differences plot for comparison of two drug assays: parametric analysis. A histogram shows the relative frequency of relative differences with the estimated Gaussian density distribution. Parametrically estimated 2.5 and 97.5 percentiles are shown with 90% CIs.

TABLE 14-9 Analysis of Distribution of *Relative* Differences for the Comparison of Drug Assays Example. $N = 65$

Total range of relative differences	−0.1598 to 0.2953		
Test for normality (Anderson-Darling test)	n.s.		
Statistical analysis	Simple nonparametric	Bootstrap	Parametric
Median	0.0467 ($P < 0.01$)		
Mean			0.0418 ($P < 0.01$)
SD			0.1109
Coefficient of skewness			+0.05
Coefficient of kurtosis			−0.60
Outlier test			n.s.
2.5 percentile	−0.1487	−0.1492	−0.1754
97.5 percentile	0.2607	0.2570	0.2591
90% CI for 2.5 percentile		−0.1627 to −0.1357	−0.2141 to −0.1368
90% CI for 97.5 percentile		0.2135 to 0.3005	0.2204 to 0.2978

percentiles were −0.18 and 0.26, respectively. The mean was 0.042 and the SD of the relative differences was 0.11. Thus we may conclude that there is a mean bias of about 4% and a random error corresponding to a CV of 11%. If we ascribe the random variation equally to the two assays, it corresponds to a random error level of $11\%/\sqrt{2} = 7.8\%$ for each assay. In the present example, this error level was considered acceptable in relation to the clinical use of the assay, and it was decided to replace the manual assay with the new, automated assay.

A modification of the histogram display of differences is a plot suggested by Krouwer and Monty[54] known as the "mountain plot." This is a plot of cumulative frequencies (*cf*%) of differences up to 50% with subsequent subtracted cumulative frequencies (100% − *cf*%). Such a plot shows in principle the same information as a histogram or frequency polygon plot. An advantage may be that the percentiles can be directly read from the plot.

Verification of Distribution of Differences in Relation to Specified Limits

In many situations in which a field method is being considered for implementation, it may be desired primarily to *verify* whether the differences in relation to the existing method are located within given specified limits rather than *estimating* the distribution of differences. For example, one may set limits corresponding to ±15% as clinically acceptable, and desire that the majority, for example, 95% of differences are located within this interval.

By counting, it may be determined whether the expected proportion of results is within the limits (i.e., 95%). One may accept percentages that do not deviate significantly from the supposed percentage at the given sample size derived from the binomial distribution (Table 14-10). For example, if 50 paired measurements have been performed in a method comparison study, and it is observed that 46 of the results (92%) are within the specified limits (e.g., ±15%), the study supports that the achieved goal has been reached, because the lower bound for acceptance is 90%. It is clear that a reasonable number of observations should be obtained for the assessment to have an acceptable power. If very few observations are at hand, the risk is high of falsely concluding that at least 95% of the observations are within the specified limits, in case it is not true (i.e., to commit a Type II error).

TABLE 14-10 Lower Bounds (One-sided 95% CI) of Observed Proportions (%) of Results Being Located Within Specified Limits for Paired Differences That Are in Accordance With the Hypothesis of at Least 95% of Differences Being Within the Limits

Difference (Bland-Altman) Plot

In recent years, the type of difference plot for evaluation of method comparison data suggested by Bland and Altman has become increasingly popular.[4] The procedure was originally introduced for comparison of measurements in clinical medicine, but the procedure has been adopted also in clinical chemistry.[65,85,88] The Bland-Altman plot is usually understood as a plot of the differences against the average results of the methods. Thus the difference plot in this version provides information on the relation between differences and concentration, which is useful to evaluate whether problems exist at certain ranges (e.g., in the high range) caused by nonlinearity of one of the methods. It may also be of interest to observe whether the differences tend to increase proportionally with the concentration, or whether they are independent of concentration. In some situations, particular interest may be directed toward the low concentration region. Information on the relation between differences and concentration is useful in the context of how to adjust for an irregularity (e.g., by changing the method with nonlinearity or by restricting the analytical measurement range). Thus this type of plot may be useful for the laboratory, whereas the DoD plot perhaps may be regarded more as directed toward the end user. The underlying error model outlined above applies also in principle to the difference plot.

The basic version of the difference plot consists of plotting the differences against the average of the measurements. Figure 14-16 shows the plot for the comparison of drug assay data. If one set of the measurements is without random measurement error, one may plot the differences against this value. If errors are present in $x1$, however, an artificial bias is induced by plotting the differences against $x1$.[5] The interval ±2 SD of the differences is often delineated around the mean difference (i.e., corresponding to the mean and the 2.5 and 97.5 percentiles considered in the parametric DoD plot).

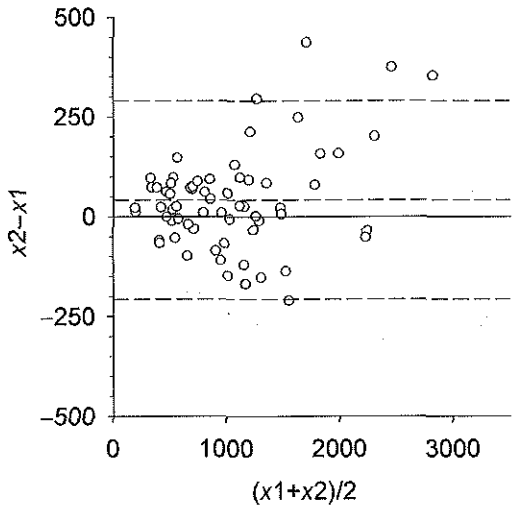

Figure 14-16 Bland-Altman plot of differences for the drug comparison example. The differences are plotted against the average concentration. The mean difference (42 nmol/L) with ±2 SD of differences is shown *(dashed lines)*.

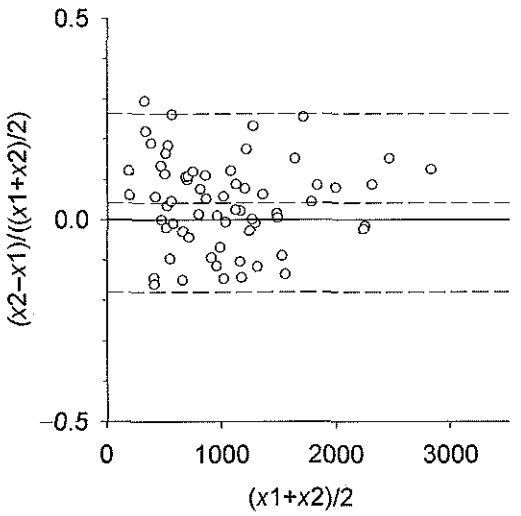

Figure 14-17 Bland-Altman plot of *relative* differences for the drug comparison example. The differences are plotted against the average concentration. The mean relative difference (0.042) with ±2 SD of relative differences is shown *(dashed lines)*.

Nonparametric limits may also be considered. The distribution of the differences as measured on the *y*-axis of the coordinate system corresponds to the relations outlined for the DoD plot, which represents a projection of the differences on the *y*-axis. A constant mean bias over the analytical measurement range changes the average concentration away from zero. The presence of random matrix-related interferences increases the width of the distribution. If the mean bias depends on the concentration or if the dispersion varies with the concentration or both, the relations become more complex, and the interval mean ±2 SD of the differences may not fit very well as a 95% interval throughout the analytical measurement range.

In the displayed Bland-Altman plot for the drug assay comparison data, there is a tendency toward increasing scatter with increasing concentration, which is a reflection of the increasing random error with the concentration level considered in detail above. Thus a plot of the relative differences against the average concentration is of relevance (Figure 14-17). Now there is a more homogeneous dispersion of values agreeing with the estimated limits for the dispersion (i.e., the relative mean difference $\pm t_{0.025,(N-1)}$ SD_{RelDif} analogous to the situation with the relative DoD plot considered above).

Focus on *relative* differences in situations with a proportional random error relationship prevents very large differences in the high concentration range from dominating the analysis and making a balanced interpretation difficult. In the low range, the proportional relationship may not necessarily hold true, and sometimes the relative difference plot makes an overcompensation in this region. It is then possible to make a truncation of the proportional relationship at some lower limit, and assume a constant SD for the differences below this limit[66] (i.e., corresponding to the relationship in Figure 14-3, *C*). In the actual example with a slightly negative correlation coefficient between relative differences and average concentration, there is a tendency toward this pattern. An alternative to the relative difference plot is to plot log differences against the average concentration, but this type of plot is more difficult to interpret.

Although it is customary to display the *estimated* limits for the differences (often mean ±2 SD_{dif}), one may as an alternative display specification limits considered being reasonable as mentioned for the DoD plot.[85] It may then be assessed whether the observed differences conform to these limits as discussed earlier (see Table 14-10). Application of the difference plot in various specific contexts has been considered.[11,98] It has also been suggested to estimate a regression line for the differences as a function of the average measurement concentration.[101]

A Caution Against Incorrect Interpretation of Paired *t*-Tests in Method Comparison Studies

In association with the difference plot, the paired *t*-test is usually applied as described above.[4] One should here be careful with regard to the interpretation. For example, consider the case shown below, in which method 2 (*x*2) measurements tend to exceed method 1 (*x*1) measurements in the low range and vice versa at high concentrations (Figure 14-18, *A*). This corresponds to a positive mean bias in the low range changing to a negative bias in the high range. In this situation, the overall averages of both sets of measurements are about identical, and the paired *t*-test yields a nonsignificant result, because the average paired difference (i.e., the mean bias) is close to zero (Table 14-11). This does not mean that the measurements are equivalent. Subjecting the data to Deming regression analysis (see the next section) clearly discloses the relation[68] (Figure 14-18, *B*). The results

of the regression analysis confirm the existence of both a systematic constant error (intercept different from zero) and a systematic proportional error (slope different from 1). Therefore the statistical significance revealed by the paired *t*-test cannot be used to indicate whether measurements are equivalent or not as also previously pointed out. The paired *t*-test is just a test for the mean bias and does not say anything about the equivalency of the measurements throughout the analytical measurement range.

Regression Analysis

Regression analysis is commonly applied in comparing the results of analytical method comparisons. Typically an experiment is carried out in which a series of paired values is collected when comparing a new method with an established method. This series of paired observations ($x1_i$, $x2_i$) is then used to establish the nature and strength of the relationship between the tests. This discussion outlines various regression models that may be used, provides criteria for when each should be used, outlines approaches for determining how many specimens to use in a given comparison, and provides guidelines for interpreting the results.

Regression analysis has the advantage that it allows the relation between the target values for the two compared methods to be studied over the full analytical measurement range. If the systematic difference between target values (i.e., the mean bias difference between the two methods or the systematic error) is related to the analyte concentration, such a relationship may not be clearly shown when using the previously mentioned types of difference plots. Although nonlinear regression analysis may be applied, the focus is usually on linear regression analysis. In linear regression analysis, it is assumed that the systematic difference between target values can be modeled as a constant systematic difference (intercept deviation from zero) combined with a proportional systematic difference (slope deviation from unity). The intercept may typically represent some average matrix-induced difference, and the proportional difference may be due to a discrepancy with regard to calibration of the methods. In situations with constant SDs of random errors, unweighted regression procedures are used (i.e., ordinary least-squares (OLR) and Deming regression analysis). For cases with SDs that are proportional to the measurement level, the corresponding weighted regression procedures are preferred.

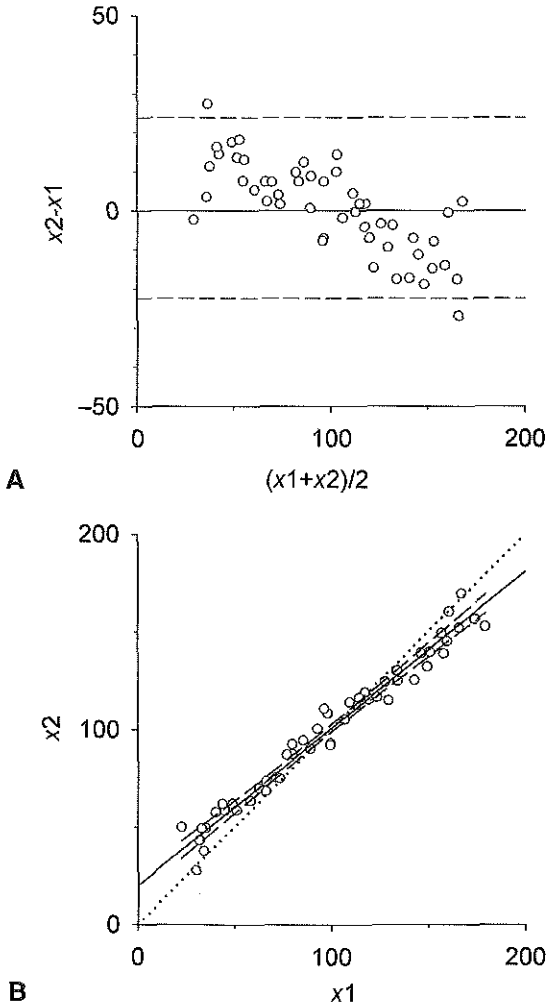

Figure 14-18 Simulated example with positive and negative differences in the low and high range, respectively: **A,** Bland-Altman plot. **B,** An x-y plot with diagonal *(dotted straight line)* and estimated Deming regression line *(solid line)* with 95% confidence curves *(dashed lines)*.

Error Models in Regression Analysis

As outlined previously, we distinguish between the measured value (x_i) and the target value (X_{Target_i}) of a sample subjected

TABLE 14-11 Comparison of Paired *t*-test Results and Deming Regression Results for a Simulated Method Comparison Example With Positive Intercept ($a_0 = 20$) and Slope Below Unity ($b = 0.80$). $N = 50$ ($x1$, $x2$) Measurements

	Paired t-Test	Regression Analysis (Deming)
Mean difference (SEM)	0.78 (1.63)	
t = Mean difference/(SEM)	0.78/1.63 = 0.48 (n.s.)	
Slope (b) (SE(b))		0.80 (0.027)
$t = (b - 1)/\text{SE}(b)$		−7.4 ($P < 0.001$)
Intercept (a_0) (SE(a_0))		20.3 (2.82)
$t = (a_0 - 0)/\text{SE}(a_0)$		7.2 ($P < 0.001$)

to analysis by a given method. In linear regression analysis we assume a linear relationship

$$X2'_{\text{Target}i} = \alpha_0 + \beta X1'_{\text{Target}i}$$

where $X1'_{\text{Target}i}$ and $X2'_{\text{Target}i}$ correspond to the target values without random bias, i.e., we have the relations:

$$X1_{\text{Target}i} = X1'_{\text{Target}i} + \text{Random-Bias1}_i$$
$$X2_{\text{Target}i} = X2'_{\text{Target}i} + \text{Random-Bias2}_i$$

This model is generally useful when the systematic difference between $X1'_{\text{Target}i}$ and $X2'_{\text{Target}i}$ depends on the measured concentration

$$X2'_{\text{Target}i} - X1'_{\text{Target}i} = \alpha_0 + (\beta - 1)X1'_{\text{Target}i}$$

The systematic difference is thus composed of a fixed part and a proportional part.

Because of random matrix-related interferences and analytical error, the individually measured pairs of values ($x1_i$, $x2_i$) will be scattered around the line expressing the relationship between $X1'_{\text{Target}i}$ and $X2'_{\text{Target}i}$. Figure 14-19 outlines schematically how the random distribution of $x1$ and $x2$ values occurs around the regression line. We have:

$$x1_i = X1_{\text{Target}i} + \varepsilon 1_i = X1'_{\text{Target}i} + \text{Random-Bias1}_i + \varepsilon 1_i$$
$$x2_i = X2_{\text{Target}i} + \varepsilon 2_i = X2'_{\text{Target}i} + \text{Random-Bias2}_i + \varepsilon 2_i$$

The random error components may be expressed as SDs, and generally we can assume that random bias and analytical components are independent for each analyte yielding the relations

$$\sigma^2_{x1} = \sigma^2_{\text{RB1}} + \sigma^2_{\text{A1}}$$
$$\sigma^2_{x2} = \sigma^2_{\text{RB2}} + \sigma^2_{\text{A2}}$$

The random bias components for method 1 and 2 may not necessarily be independent. They may also not be normally distributed, which is less likely as regards the analytical components. Thus when applying a regression procedure, the explicit assumptions to take into account should be considered. In situations without random bias components of any significance, the relationships simplify to

$$\sigma^2_{x1} = \sigma^2_{\text{A1}}$$
$$\sigma^2_{x2} = \sigma^2_{\text{A2}}$$

In this situation, it can usually be assumed that the error distributions are normal, and the standard deviations may be known from quality control data.

Another methodological problem concerns the question whether the dispersion of the random error components is constant or changes with the analyte concentration as considered previously in the difference plot sections. For most clinical chemical compounds, the analytical SDs vary with the measured concentration, and this relationship may also apply to the random-bias components. In cases with a considerable range (i.e., a decade or more), this phenomenon should also be taken into account when applying a regression analysis. Figure 14-20 schematically shows how the dispersions may increase proportionally with concentration.

Deming Regression Analysis and Ordinary Least-Squares Regression Analysis (OLR) (Constant SDs)

To estimate the relationship between the target values accurately (i.e., a_0 for α_0 and b for β), a regression procedure taking errors in both $x1$ and $x2$ into account is preferable

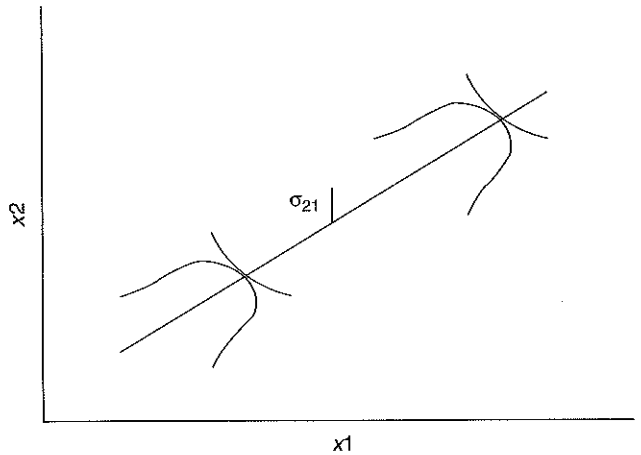

Figure 14-19 Outline of the relation between $x1$ and $x2$ values measured by two methods subject to random errors with constant standard deviations over the analytical measurement range. A linear relationship between the target values ($X1'_{\text{Target}i}$, $X2'_{\text{Target}i}$) is presumed. The $x1_i$ and $x2_i$ values are Gaussian distributed around $X1'_{\text{Target}i}$ and $X2'_{\text{Target}i}$, respectively, as schematically shown. σ_{21} (σ_{yx}) is demarcated.

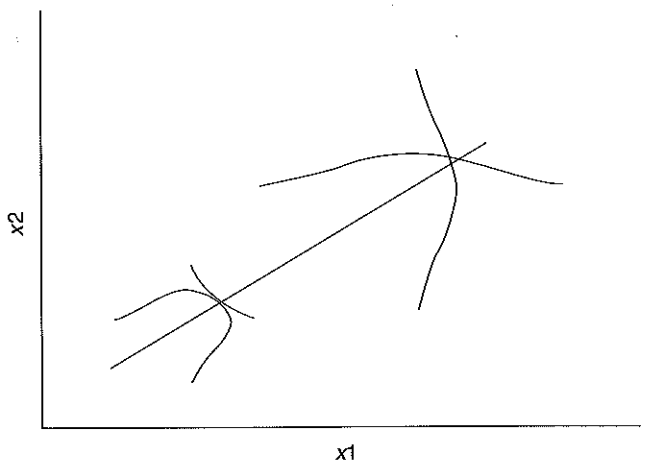

Figure 14-20 Outline of the relation between $x1$ and $x2$ values measured by two methods subject to proportional random errors. A linear relationship between the target values is assumed. The $x1_i$ and $x2_i$ values are Gaussian distributed around $X1'_{\text{Target}i}$ and $X2'_{\text{Target}i}$, respectively, with increasing scatter at higher concentrations as schematically shown.

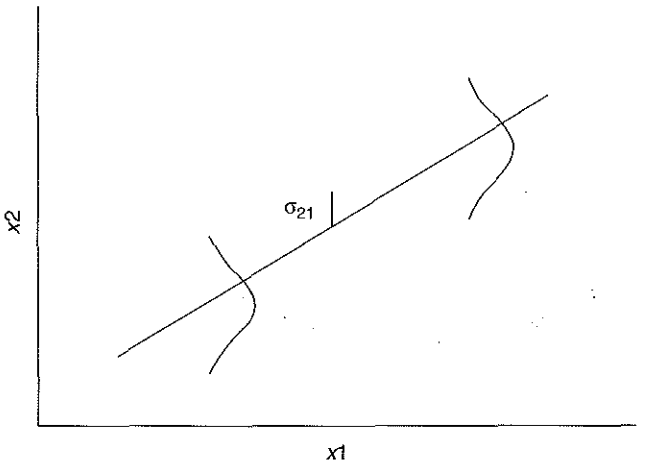

Figure 14-21 The model assumed in ordinary OLR. The $x2$ values are Gaussian distributed around the line with constant standard deviation over the analytical measurement range. The $x1$ values are assumed to be without random error. σ_{21} (σ_{yx}) is shown.

(Figures 14-19 and 14-20). In the statistical literature, this type of regression analysis is called errors-in-variables analysis or is referred to as structural or functional relationship models.[46] Various modifications exist, comprising both parametric and nonparametric approaches. In clinical chemistry, a parametric approach described in the following is usually called the Deming method.[12,17] However, the most widely used regression procedure in method comparison studies, OLR, does not take errors in $x1$ into account but is based on the assumption that only the $x2$ measurements are subject to random errors (Figure 14-21). In the Deming procedure, the sum of squared distances from measured sets of values ($x1_i$, $x2_i$) to the regression line is minimized at an angle determined by the ratio between the standard deviations for the random variations of $x1$ and $x2$. It can be theoretically proven that given Gaussian error distributions, this estimation procedure is optimal. In Figure 14-22, the symmetric case is illustrated with a regression slope of 1 and equal standard deviations for the random variations of $x1$ and $x2$, in which case the sum of squared distances is minimized orthogonally in relation to the line. In OLR, the sum of squared distances is minimized in the vertical direction to the line (Figure 14-22). It can be proven theoretically that neglect of the random error in $x1$ induces a downward biased slope estimate

$$\beta' = \beta\left(\sigma^2_{X1'\text{target}} \Big/ \left(\sigma^2_{X1'\text{target}} + \sigma^2_{x1}\right)\right)$$
$$= \beta \Big/ \left[1+\left(\sigma_{x1}/\sigma_{X1'\text{target}}\right)^2\right]$$

where $\sigma_{X1'\text{target}}$ is the standard deviation of $X1'$ target values.[97] According to the formula, the amount of bias depends on the ratio between the standard deviation for the random error in $x1$ and the standard deviation of the $X1'$ target values. In situations with a wide range of $X1'$ target values, this bias may be negligible, and OLR may be used for estimation of slope and intercept despite the assumption of a wrong error model. Figure 14-23 shows the bias as a function of the ratio of the random error standard deviation to the standard deviation of the $X1'$ target value dispersion. For a ratio up to 0.1, the bias is less than 1%. At a ratio of 0.33, the bias amounts to 10%, and then increases further for increasing ratios.

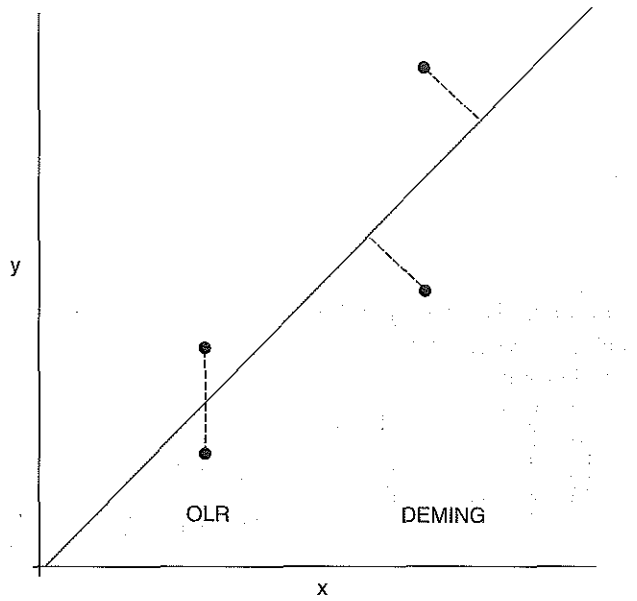

Figure 14-22 In OLR, the sum of squared deviations from the line is minimized in the vertical direction. In Deming regression analysis, the sum of squared deviations is minimized at an angle to the line depending on the random error ratio. Here the symmetric case is displayed with orthogonal deviations. *(From Linnet K. The performance of Deming regression analysis in case of a misspecified analytical error ratio. Clin Chem 1998;44:1024-1031 [Figure 1]).*

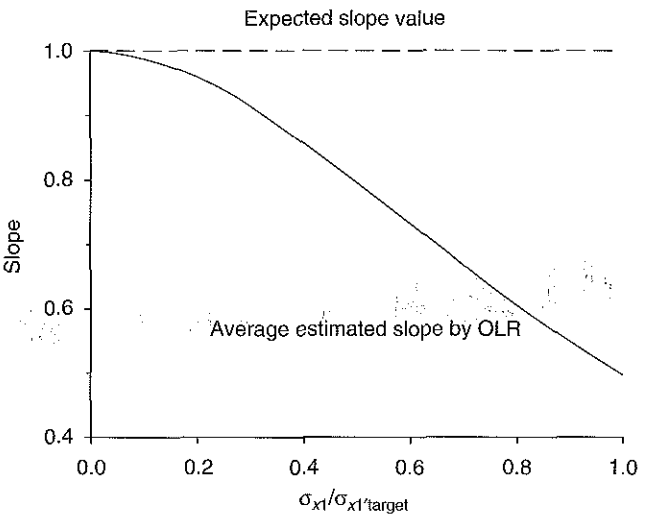

Figure 14-23 Relations between the true (expected) slope value and the average estimated slope by OLR. The bias of the OLR slope estimate increases negatively for increasing ratios of the standard deviation random error in $X1$ to the standard deviation of the $X1$ target value distribution.

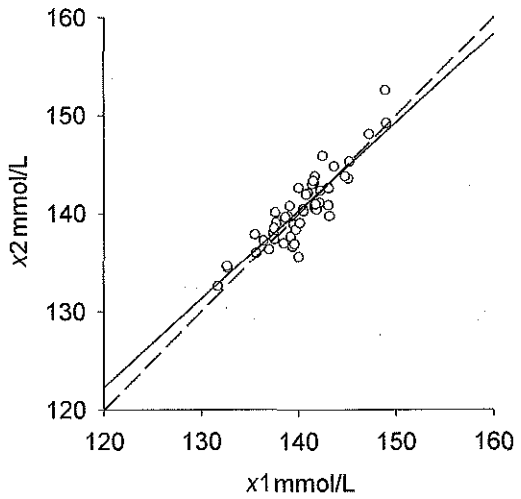

Figure 14-24 Simulated comparison of two sodium methods. The solid line indicates the average estimated OLR line, and the dashed line is the identity line. Even though there is no systematic difference between the two methods, the average OLR line deviates from the identity line corresponding to a downward slope bias of about 10%.

Example

As an illustration of the bias problem associated with application of the OLR procedure, we will study by simulation the comparison of two sodium methods. Fifty paired measurements are simulated. It is assumed that there is no systematic difference between the measurements, and we will expect an average slope estimate of 1.0 for 1000 repeated experiments. The mean value is 140.5 mmol/L corresponding to the mean of a reference interval 136 to 145 mmol/L. The dispersion of the target values was set to 3.8 mmol/L, which corresponds to a range exceeding the reference interval by about 5 mmol/L in each direction, corresponding to inclusion of some pathological samples. The analytical SDs for the methods are presumed constant throughout the analytical measurement range with values of 1.27 mmol/L corresponding to CVs of 0.9% at the mean 140.5 mmol/L. The average estimated regression line for the 1000 repetitions corresponds to the solid line in Figure 14-24, which is tilted downward corresponding to a slope value of 0.90 (i.e., 10% lower than the expected value of 1.0). The slope bias of −10% occurs, because the ratio between the SD of the random error in x to the SD of the dispersion of the target X' values is 0.33.

In the example presented above, the ratio of the analytical SD to the SD of the target value distribution is large because of the tight physiological regulation of electrolyte concentrations, which means that the biological variation is limited. Most other types of analytes exhibit wider distributions, and the ratio of error to target value distribution is smaller. For example, for analytes with a distribution of more than 1 decade and an analytical error corresponding to a CV of 5% at the middle of the analytical measurement range, the OLR slope bias amounts to about −1%.

Whether this is considered a problem may depend on the situation. In the context of assessing the ability to trace analytical methods from regression analysis of paired patient sample measurements, an error of 1% solely because of the applied regression procedure would indeed constitute a problem (see Traceability and Measurement Uncertainty later in this chapter).

Computation Procedures for OLR and Deming Regression

Assuming no errors in $x1$ and a Gaussian error distribution of $x2$ with constant standard deviation throughout the analytical measurement range, OLR is the optimal estimation procedure as proved by Gauss in the eighteenth century. About 50 years later, the first version of the errors-in-variables regression model was outlined by Adcock[1] and later supplemented by Kummel.[57] It should be noted for these parametric procedures that only the error distributions must be normal. The least-squares principle does not presume normality to be applied, but it is optimal under normality conditions, and the nominal Type I errors for the associated statistical tests for slope and intercept hold true under this assumption. The procedures are generally robust toward deviations from normality, but they are sensitive toward outliers because of the squaring principle. Finally the distribution of the target values of $x1$ and $x2$ does not have to be normal. A uniform distribution over the analytical measurement range is generally of advantage, but the distribution may in principle take any form.

It can be proved theoretically that the lines that minimize the sum of squared distances from the line in the two situations can be estimated as described below.[46] In both cases the mean values, the sum of squared deviations, and a sum of cross products should be computed:

$$x1_m = \sum x1_i/N \qquad x2_m = \sum x2_i/N$$

$$u = \sum (x1_i - x1_m)^2 \qquad q = \sum (x2_i - x2_m)^2$$

$$p = \sum (x1_i - x1_m)(x2_i - x2_m)$$

For OLR we have:

$$b = p/u \qquad a_0 = x2_m - bx1_m$$

and so

$$X2'_{\text{Targetesti}} = a_0 + bx1_i$$

$X2'_{\text{Targetesti}}$ refers to the *estimated* $X2'$ target value for a given $x1_i$ according to the regression equation (under the OLR model $x1_i$ and $X1'_{\text{Target}i}$ are identical). In case of duplicate sets of measurements, each $x1_i$ and $x2_i$ represents the mean of individual measurements ($x1 = (x1_{1i} + x1_{2i})/2$ and $x2_i = (x2_{1i} + x2_{2i})/2$).

To compute the slope in Deming regression analysis, the ratio between the standard deviations of the random errors of $x1$ and $x2$ is necessary, i.e.,

$$\lambda = (\sigma^2_{\text{RB1}} + \sigma^2_{\text{A1}})/(\sigma^2_{\text{RB2}} + \sigma^2_{\text{A2}})$$

(assuming independence of the random-bias terms).

Analytical standard deviations can be estimated from duplicate sets of measurements as:

$$SD_{A1}^2 = (1/2N)\sum(x1_{2i} - x1_{1i})^2$$

$$SD_{A2}^2 = (1/2N)\sum(x2_{2i} - x2_{1i})^2$$

or they may be available from quality control data.

If a specific value for λ is not available and the two field methods that are compared are likely to be associated with random error levels of the same order of magnitude, λ can be set to 1. The Deming procedure is generally relatively insensitive to a misspecification of the λ value.[67] The slope and intercept may now be derived as

$$b = \left[(\lambda q - u) + \left[(u - \lambda q)^2 + 4\lambda p^2\right]^{0.5}\right] \Big/ (2\lambda p)$$

$$a_0 = x2_m - bx1_m$$

and so

$$X2'_{\text{Targetest}i} = a_0 + bX1'_{\text{Targetest}i}$$

For both procedures, we may evaluate the standard deviation of the dispersion in the *vertical* direction around the line (commonly denoted SD_{yx} and here given as SD_{21}). We have

$$SD_{21} = \left[\sum(x2_i - X2'_{\text{Targetest}i})^2 / (N-2)\right]^{0.5}$$

For the OLR procedure we may further derive the standard errors of the slope and intercept estimate as follows

$$SE(b) = SD_{21}/\sqrt{u} \quad SE(a_0) = SD_{21}\left[1/N + x1_m^2/u\right]^{0.5}$$

For the OLR procedure, given that the assumptions are fulfilled (which they almost never are), these SEs are exact. For the Deming procedure, they apply approximately. More correct formulas have been given[99] or they can be conveniently derived by a computerized method (see later in this chapter). For both OLR and Deming regression analysis, the correct interpretation of SD_{21} is important, but quite often it is misinterpreted (see the next section).

Evaluation of the Random Error Around an Estimated Regression Line

The estimated slope and intercept provide an estimate of the systematic difference or error between two methods over the analytical measurement range. Additionally an estimate of the random error is important. As mentioned above, it is commonplace to consider the dispersion around the line in the vertical direction, which is quantified as SD_{yx} (here denoted SD_{21}). SD_{21} has originally been introduced in the context of OLR, but it may as well be considered in relation to Deming regression analysis.

Interpreting SD_{yx} (SD_{21}) With Random Error only in x2

In the model assumed in OLR, we only have random errors associated with $x2$ measurements (see Figure 14-21). This situation occurs infrequently in practice, but it can happen (e.g., when a set of reference materials is available that have been determined repetitively by a reference method), so that in practice there is no random measurement error present. In this case, the scatter around the line solely reflects the random error of $x2$ measurements. If there are no random matrix-related interferences, the random error equals the analytical imprecision, and we have

$$\sigma_{21} = \sigma_{A2}$$

If random matrix-related interferences are present, we have

$$\sigma_{21}^2 = \sigma_{A2}^2 + \sigma_{RB2}^2$$

where σ_{RB2} is the standard deviation of the random matrix-related effects, which are here supposed to be normally distributed and independent of method imprecision.

Interpreting SD_{yx} (SD_{21}) With Random Errors in Both x1 and x2

With regard to σ_{21}, we have here without sample-related random effects

$$\sigma_{21}^2 = \beta^2\sigma_{A1}^2 + \sigma_{A2}^2$$

Thus σ_{21} reflects both the random error in $x1$ (with a rescaling) and in $x2$. Often β is close to unity, and in this case σ_{21}^2 becomes approximately the sum of the individual squared standard deviations.[73] This relation holds true for both Deming and OLR analysis. Frequently, OLR is applied in situations associated with random measurement error in both $x1$ and $x2$, and in these situations σ_{21} reflects the errors of both.

The presence of sample-related random interferences in both $x1$ and $x2$ gives the following expression

$$\sigma_{21}^2 = \left[\beta^2\sigma_{A1}^2 + \sigma_{A2}^2\right] + \left[\beta^2\sigma_{RB1}^2 + \sigma_{RB2}^2\right]$$

Thus, the σ_{21} value is influenced by the slope value, the analytical error components σ_{A1} and σ_{A2} (grouped in the first bracket) and σ_{RB1} and σ_{RB2} (grouped in the second bracket). In many cases, the slope is close to unity, in which case we have simple addition of the components. As mentioned earlier, the matrix-related random interferences may not be independent. In this case, simple addition of the components is not correct, because a covariance term should be included. However, in a real case, we can estimate the combined effect corresponding to the bracket term. Information on the analytical components is usually available, either from duplicate sets of measurements or from quality control data. On this basis, the combined random bias term in the second bracket can be derived by subtracting the analytical components from σ_{21}. Overall, it can be judged whether the total random error is acceptable or not. The systematic difference can be adjusted for relatively easily by a rescaling of one of the sets of measurements. However, if the random error term is very large, such a rescaling does not ensure equivalency of measurements with regard to individual samples. Thus it is important to assess both the systematic difference and the random error when deciding whether a new field method can replace an existing one. Figure 14-25 shows the random distributions around the regression lines for simulated

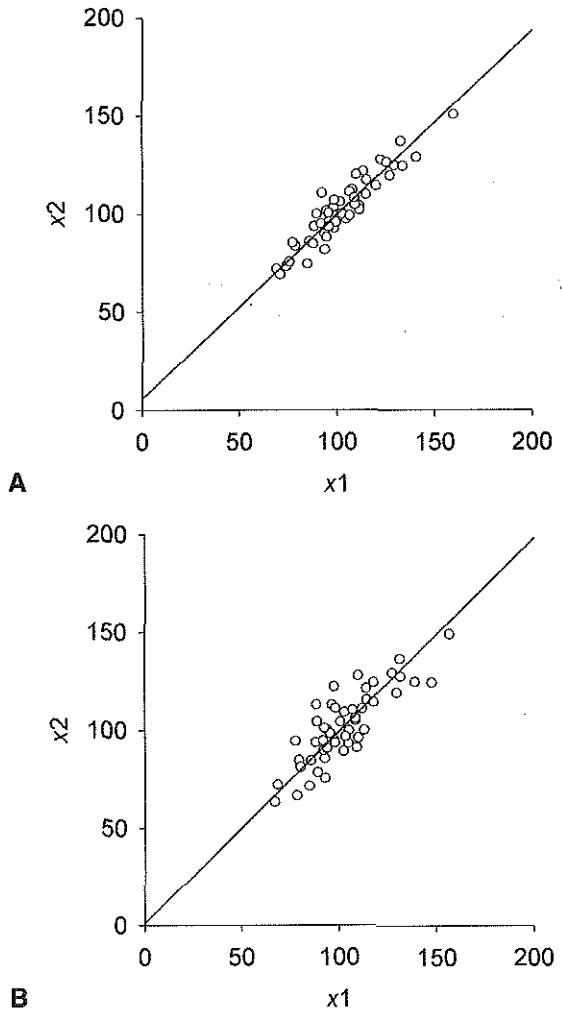

Figure 14-25 Simulated examples that illustrate the effect of sample-related random interferences in a scatter plot with regression analysis. **A,** *x*1 and *x*2 are subject to only analytical errors. **B,** Additional random bias of the same magnitude is present, which results in a wider scatter around the line.

examples with only analytical error (A) and both analytical error and random bias of an equal magnitude (B). In a roughly symmetric situation with a slope close to unity and two field methods of presumed equal specificity and precision, the total random error expressed as SD_{21} may be subdivided into component errors associated with each test by dividing with the square root of two. One may then assess the random error levels in relation to stated goals.

Assessment of Outliers

The principle of minimizing the sum of squared distances from the line makes the described regression procedures sensitive toward outliers, and an assessment of the occurrence of outliers should be carried out routinely. The distance from a suspected outlier to the line is recorded in standard deviation units, and rejection of the outlier is performed if the distance exceeds a predetermined limit (e.g., 3 or 4 standard deviation units). In the case of OLR, the standard deviation unit equals SD_{21}, and the vertical distance is considered. For Deming regression analysis, the unit is the standard deviation of the deviation of the points from the line at an angle determined by the error variance ratio λ. A plot of these deviations, a so-called residuals plot, conveniently illustrates the occurrence of outliers.[64] Figure 14-26, *A* illustrates a Deming regression analysis example with occurrence of an outlier and the associated residuals plot (B), which clearly shows the outlier pattern. In this example, the residuals plot was standardized to unit standard deviation. Using in this example an outlier limit of 4 standard deviation units, the outlier was rejected and a reanalysis was undertaken. In this example, rejection of the outlier changed the slope from 1.14 to 1.03. With regard to outliers, these measurements should not just be rejected automatically, but the reason for their presence should be scrutinized.

The Correlation Coefficient

Having outlined the random error components related to regression analysis, some comments on the correlation coefficient may be appropriate. The ordinary correlation coefficient ρ, also called the Pearson product moment correlation coefficient, is estimated as *r* from sums of squared deviations for *x*1 and *x*2 values as follows using the same notation as above[97]

$$r = p/[uq]^{0.5}$$

Looking at the theoretical model, ρ is related to the ratio between the standard deviations of the distributions of target values ($\sigma_{X1'target}$ and $\sigma_{X2'target}$) and the associated independent total random error components (σ_{x1} and σ_{x2})[7]

$$\rho = \sigma_{X1'target}\sigma_{X2'target}/\left[\left(\sigma^2_{X1'target}+\sigma^2_{x1}\right)\left(\sigma^2_{X2'target}+\sigma^2_{x2}\right)\right]^{0.5}$$

The total random error components comprise both imprecision error and sample-related random interferences (i.e., $\sigma^2_{x1} = \sigma^2_{A1} + \sigma^2_{RB1}$ and $\sigma^2_{x2} = \sigma^2_{A2} + \sigma^2_{RB2}$). Thus ρ is a *relative* indicator of the amount of dispersion around the regression line. If the range of values is short, ρ tends to be low and vice versa for a long range of values. For example, consider simulated examples, where the random errors of *x*1 and *x*2 are the same, but the width of the distributions of target values differs (Figure 14-27, *A* and *B*). In (A) the target values are uniformly distributed over the range 1 to 3, and in (B) the range is 1 to 6. The random error SD is presumed constant, and it is in both cases set to 0.15 for both *x*1 and *x*2 corresponding to a CV of 5% at the level 3. Given sets of 50 paired measurements, the correlation coefficient is 0.93 in case (A) and 0.99 in case (B). Further, a single point located outside the range of the rest of the observations exerts a strong influence (Figure 14-27, *C*). In (C) 49 of the observations are distributed within the range 1 to 3 with a single point located apart from the others around the value 6, other factors being equal. The correlation coefficient here takes an intermediate value, 0.97. Thus a single point located away from the rest has a strong influence (a so-called influential point). Notice that it is not an outlying point, just an aberrant point with regard to the range.

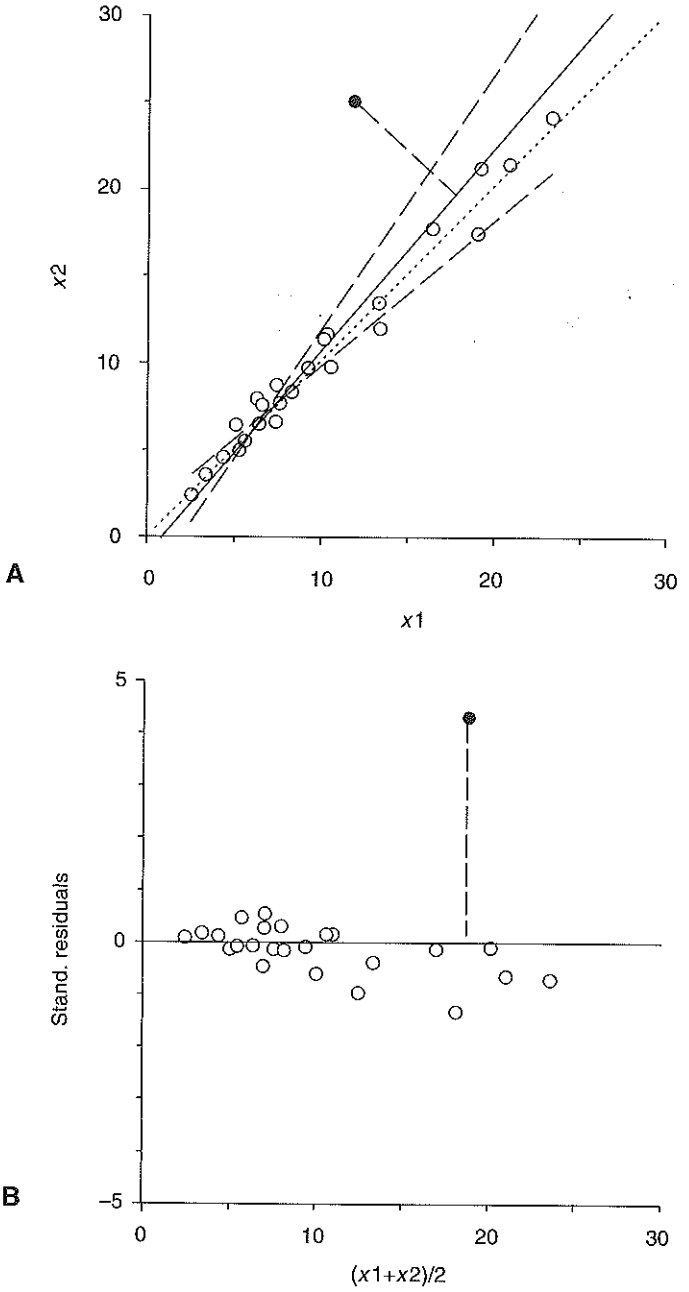

Figure 14-26 **A,** A scatter plot with the Deming regression line *(solid line)* with an outlier *(filled point)*. The dotted straight line is the diagonal, and the curved dashed lines demarcate the 95% confidence region. **B,** Standardized residuals plot with indication of the outlier.

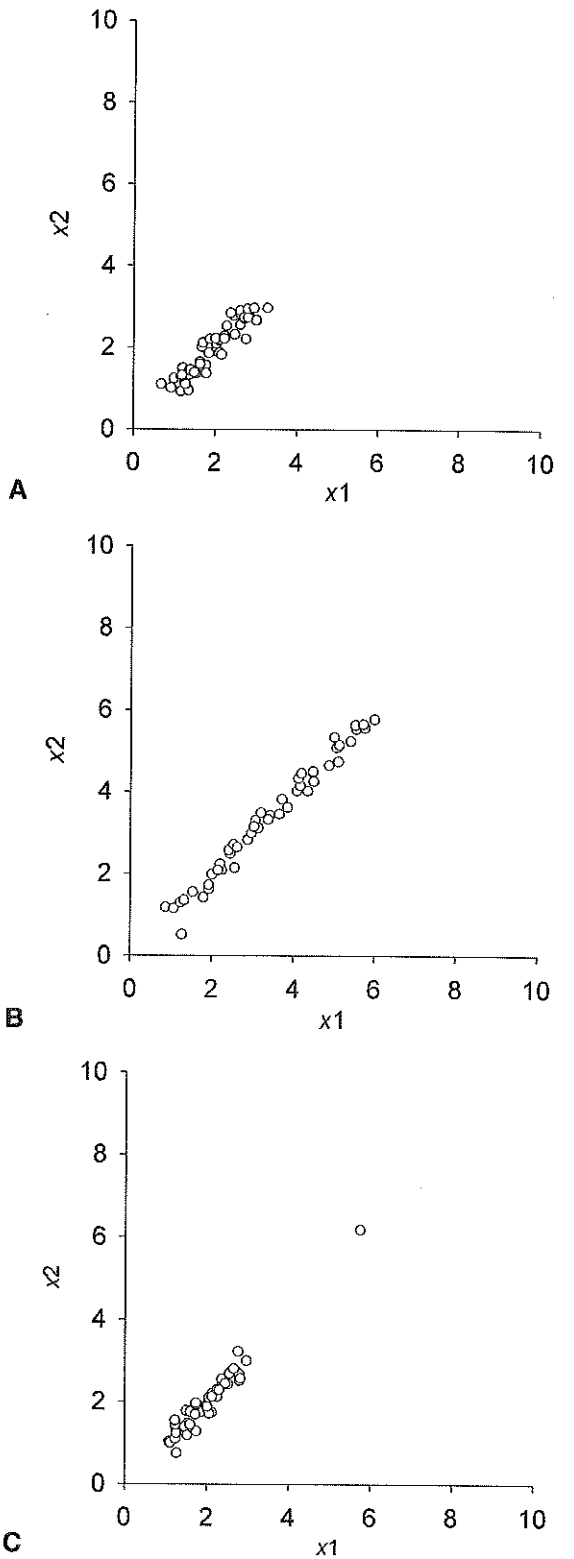

Figure 14-27 Scatter plots illustrating the effect of the range on the value of the correlation coefficient ρ. **A,** The target values are uniformly distributed over the range 1 to 3 with random errors of both *x*1 and *x*2 corresponding to an SD of 5% of the target value at 3 (constant error standard deviations). **B,** The range is extended to 1 to 6 with the same random error levels. The correlation coefficient equals 0.93 in **A** and 0.99 in **B**. In **C** the effect of a single aberrant point is shown. Forty-nine of the target values are distributed over the range 1 to 3 with a single point at 6. The correlation coefficient is 0.97.

Although σ_{21} is the relevant measure for random error in method comparison studies, ρ is still widely used as a supposed measure of agreement between two methods. It should be noted that a systematic difference is not expressed through ρ; thus even though the correlation coefficient is very high, there may be a considerable bias between the measurements of two methods.

Regression Analysis in Case of Proportional Random Errors

As discussed in relation to the precision profile, for analytes with extended ranges (e.g., 1 or several decades), the analytical standard deviation is seldom constant. Rather a proportional relationship may apply. This may also be true for the random bias components. In this situation, the regression procedures described above may still be used, but they are not optimal because the standard errors of slope and intercept become larger than is the case when applying a weighted form of regression analysis. The optimal approaches are weighted forms of regression analysis that take into account the relationship between random error and analyte concentration. Given a proportional relationship, a weighted procedure assigns larger weights to observations in the low range; the low-range observations are more precise than measurements at higher concentrations that are subject to larger random errors. More specifically, weights are applied in the computations that are inversely proportional to the squared standard deviations (variances) that express the random error. In the weighted form of least-squares regression analysis (WLR) the distances from $(x1_i, x2_i)$ to the line in the vertical direction are inversely weighted according to the squared SD_A value at the given concentration level (Figure 14-28).

The following computations are performed

$$x1_{mw} = \sum w_i x1_i / \sum w_i \qquad x2_{mw} = \sum w_i x2_i / \sum w_i$$

$$u_w = \sum w_i (x1_i - x1_{mw})^2 \qquad q_w = \sum w_i (x2_i - x2_{mw})^2$$

$$p_w = \sum w_i (x1_i - x1_{mw})(x2_i - x2_{mw})$$

$$b = p_w / u_w \qquad a_0 = x2_{mw} - b x1_{mw}$$

$$X2'_{\text{Targetest}i} = a_0 + b x1_i$$

The weights (w_i) are inversely proportional to the squared standard deviation of random errors of $x2$ measurements at a given concentration. These standard devations are assumed to be a function $(h(\cdot))$ of $x1$:

$$\sigma_{A2} = k_{A2} h(x1_i) \qquad w_i = [h(x1_i)]^{-2}$$

$$\sigma_{RB2} = k_{RB2} h(x1_i)$$

where k_{A2} and k_{RB2} are proportionality factors and $w_i = [h(x1_i)]^{-2}$.[31,66] Alternatively, weighting might be given as a function of $X2'_{\text{Targetest}}$ determined iteratively, which provides essentially the same results apart from different proportionality constants. For the proportional standard deviation case, which is assumed to hold true in the present context, $w_i = 1/x1_i^2$. The proportionality factor is estimated from the dispersion around the line in the vertical direction

$$k = \left[\sum (x2_i - X2'_{\text{Targetest}i})^2 w_i / (N - 2)\right]^{0.5}$$

The standard errors of slope and intercept are[31,66]

$$\text{SE}(b) = k/\sqrt{u_w} \qquad \text{SE}(a_0 = k\left[1/\sum w_i + x_{mw}^2/u_w\right])^{0.5}$$

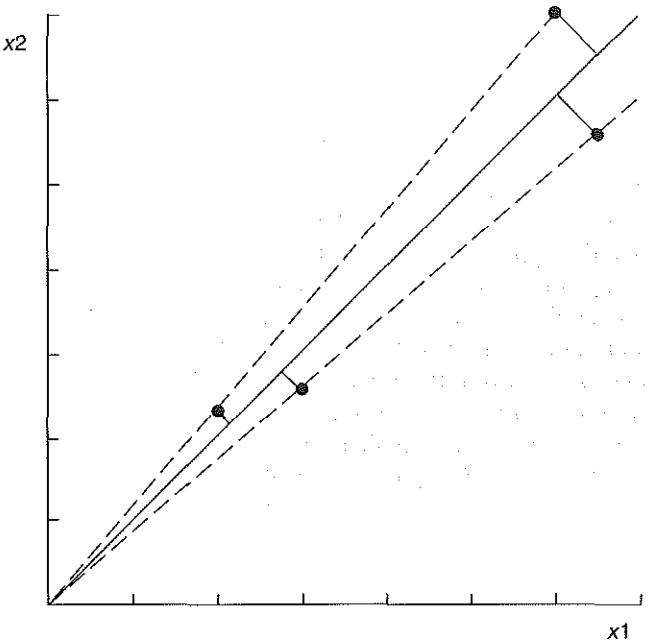

Figure 14-28 Distances from data points to the line in the vertical direction in WLR assuming proportional standard deviations for random errors in $x2$ and no random error in $x1$. *(From Linnet K. Necessary sample size for method comparison studies based on regression analysis. Clin Chem 1999;45:882-94.)*

The Deming method can also be carried out in a weighted form (e.g., assuming proportional standard deviations). In the weighted modification of the Deming procedure, distances from $(x1_i, x2_i)$ to the line are inversely weighted according to the squared standard deviations at a given concentration (Figure 14-29). The regression procedures are most conveniently performed using dedicated software, which is available on the book's accompanying Evolve site.

For the weighted Deming procedure, the slope and intercept are estimated as[64]

$$b = \left[(\lambda q_w - u_w) + \left[(u_w - \lambda q_w)^2 + 4\lambda p_w^2\right]^{0.5}\right] / 2\lambda p_w$$

$$a_0 = x2_{mw} - b x1_{mw}$$

$$X2'_{\text{Targetest}i} = a_0 + b X1'_{\text{Targetest}i}$$

It is here presumed that the *ratio* between the squared standard deviations for the random error components

$$\lambda = (\sigma_{RB1}^2 + \sigma_{A1}^2) / (\sigma_{RB2}^2 + \sigma_{A2}^2)$$

is constant throughout the analytical measurement range. The standard deviations are functions of the target values

$$\sigma_{A1} = k_{A1}h(X1'_{Targeti}) \text{ and } \sigma_{A2} = k_{A2}h(X2'_{Targeti})$$

$$\sigma_{RB1} = k_{RB1}h(X1'_{Targeti}) \text{ and } \sigma_{RB2} = k_{RB2}h(X2'_{Targeti})$$

Assuming a proportional relationship, the weights w_i $(= 1/[(X1'_{Targetesti} + \lambda X2'_{Targetesti})/(1+\lambda)]^2)$ are obtained by an iterative approach as described.[64,66]

For the weighted Deming procedure, general formulas for standard errors of slope and intercept are complicated, and computerized methods (e.g., jackknife or bootstrap) may be applied in their estimation (available on the book's accompanying Evolve site). Using these computerized approaches, a 95% confidence region around the line may also be estimated (Figure 14-30). The confidence region as outlined here refers to the CIs for estimated $X2'$ target values in relation to given $X1'$ target values and is accordingly not a 95% region for the individual paired observations (i.e., it is not a prediction region). It is observed that the interval is most narrow at a level corresponding to the weighted mean of $x1$ values and widens toward the extremes of the $x1$ range, especially at high concentrations where the random error is largest. For a simplified situation with a slope close to unity and equal CVs for random error components of $x1$ and $x2$, the formulas given under WLR approximately apply.

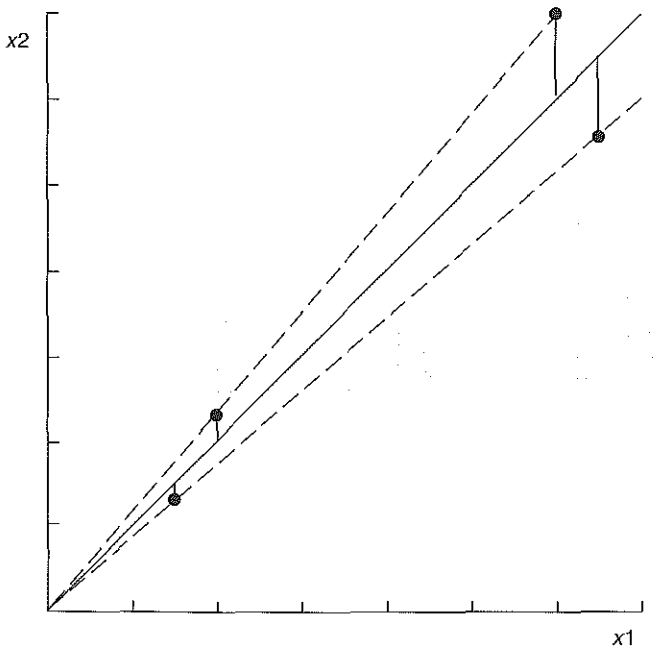

Figure 14-29 Distances from data points to the line in weighted Deming regression assuming proportional random errors in $x1$ and $x2$. The symmetric case is illustrated with equal random errors and a slope of unity yielding orthogonal projections onto the line. *(From Linnet K. Necessary sample size for method comparison studies based on regression analysis. Clin Chem 1999;45:882-94.)*

Determination of the Random Error Around an Estimated Regression Line in Case of Proportional Random Errors

In regression analysis with proportional random errors, we will also consider the dispersion around the line in the vertical direction. SD_{21} is dependent on the measured concentration. Supposing a proportional error relationship and an intercept of the regression line close to zero, SD_{21} can be characterized by a proportionality factor.[31,66]

Relations with Random Error Only in $x2$

In the model assumed in WLR, we only have random errors associated with $x2$ measurements. If there are no random matrix-related interferences, the random error equals the analytical imprecision, and we have

$$CV_{21} = CV_{A2}$$

If random matrix-related interferences are present, we have

$$CV_{21}^2 = CV_{A2}^2 + CV_{RB2}^2$$

where CV_{RB2} is the coefficient of variation for the random matrix-related effects, which are here supposed to be normally distributed and independent of method imprecision.

Relations with Random Errors in Both $x1$ and $x2$

Assuming there are random errors in $x1$ and $x2$ without sample-related random effects, CV_{21} can be determined as follows

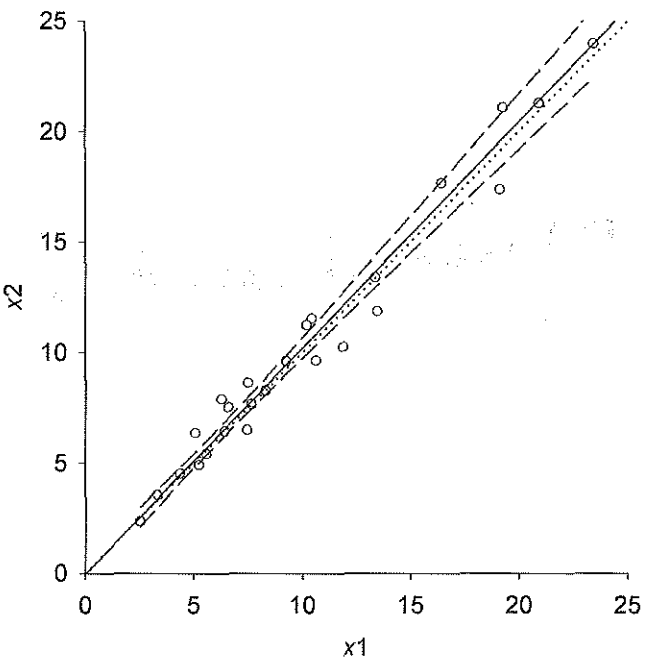

Figure 14-30 An example of application of weighted Deming regression analysis. The solid line is the estimated regression line, and the dotted line is the line of identity. The estimated 95% confidence bands obtained by the jackknife approach are the curved dashed lines.

$$CV_{21}^2 = CV_{A1}^2 + CV_{A2}^2$$

Thus CV_{21} reflects both the random error in $x1$and in $x2$. In case of proportional errors, there is no rescaling of the $x1$ error contribution. This relation holds true for both weighted Deming and WLR analysis. Frequently, WLR is applied in situations associated with random measurement error in both $x1$ and $x2$, and in these situations CV_{21} reflects the errors of both.

The presence of proportional sample-related random interferences in both $x1$ and $x2$ gives the following expression

$$CV_{21}^2 = [CV_{A1}^2 + CV_{A2}^2] + [CV_{RB1}^2 + CV_{RB2}^2]$$

As mentioned earlier, the matrix-related random interferences may not be independent. In this case, simple addition of the components is not correct, because a covariance term should be included. However, we can estimate the combined effect corresponding to the bracket term, which then strictly refers to the CV of the differences ($CV_{RB2-RB1}^2$). As in the case with constant standard deviations, information on the analytical components is usually available, either from duplicate sets of measurements or from quality control data, and the combined random bias term in the second bracket can then be derived by subtracting the analytical component from CV_{21}. Systematic and random errors can then be determined, and it can be decided whether a new field method can replace an existing one. Figure 14-31 shows an example with proportional random errors around the regression line.

In a situation with proportional random errors, a weighted modification of the correlation coefficient can be computed from sums of squared deviations for $x1$ and $x2$ values as follows

$$r_w = p_w/[u_w q_w]^{0.5}$$

Adjustments for Recalibration

Having estimated a linear relationship between two field methods, one may wish to recalibrate one of the methods in relation to the other (e.g., for method 2 one may make the *adjustment*)

$$x2_{rec} = (x2 - a_0)/b$$

where $x2_{rec}$ is the recalibrated $x2$ value. The systematic bias is now adjusted between the methods, and it is of interest to study the random error elements. Figures 14-32, *A* and 14-33, *A* show two simulated situations in which $\sigma_{A1} = \sigma_{A2} = 5$ and $\sigma_{RB1} = \sigma_{RB2} = 5$. In Figures 14-32, *A* and 14-33, *A* the slopes are 1.5 and 0.5, respectively. The random error of the differences between the values of method 1 and the recalibrated $x2$ values ($x2_{rec} - x1$) is observed from the displayed recalibration difference plots (Figures 14-32, *B* and 14-33, *B*). It is evident that in the case with a slope of 0.5, the dispersion of the differences is largest. This is due to the rescaling of the $x2$ values, which leads to an associated rescaling of the random error. We have

$$\sigma_{A2rec} = \sigma_{A2}/\beta \text{ and } \sigma_{RB2rec} = \sigma_{RB2}/\beta$$

Thus in the case with a slope value below unity, the random error of the rescaled value is amplified, and vice versa for a

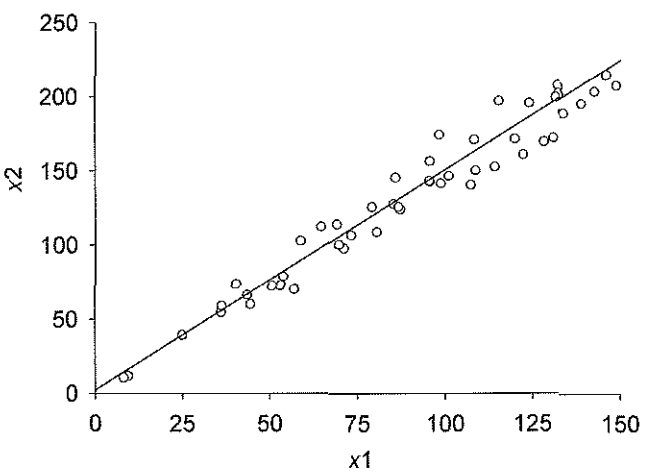

Figure 14-31 *An example of proportional random errors* around a regression line estimated by the weighted Deming approach.

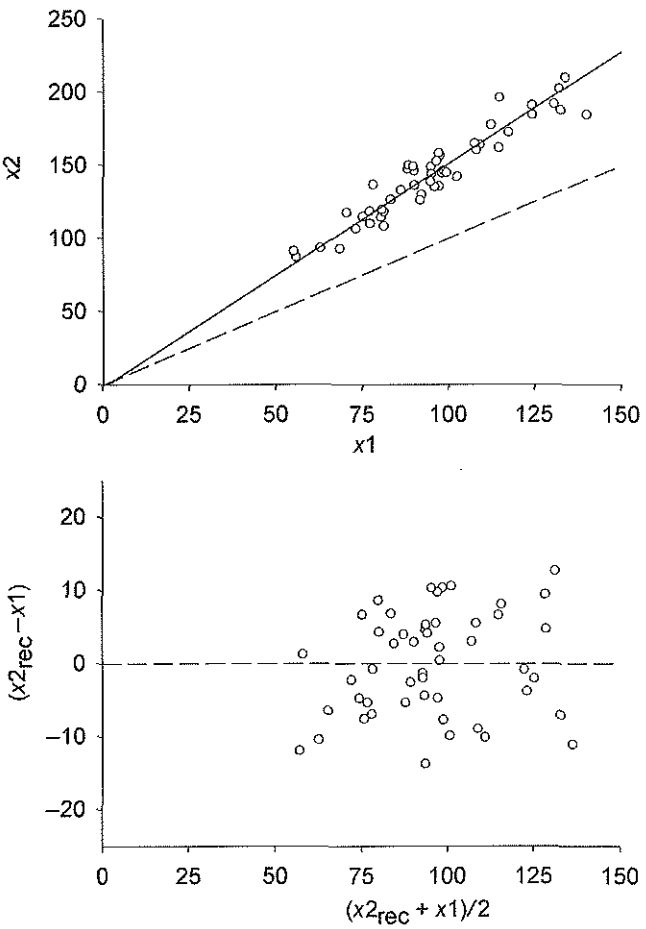

Figure 14-32 *Scatter* plot *(top)* and recalibration difference plot *(bottom)* of ($x2_{rec} - x1$) differences against ($x2_{rec} + x1$)/2 for *situations corresponding* to one simulation run of $N = 50$ ($x1$, $x2$) sets for the following parameter values: $\alpha_0 = 0$, $\beta = 1.5$, $\sigma_{x1} = 5$, and $\sigma_{x2} = 5$.

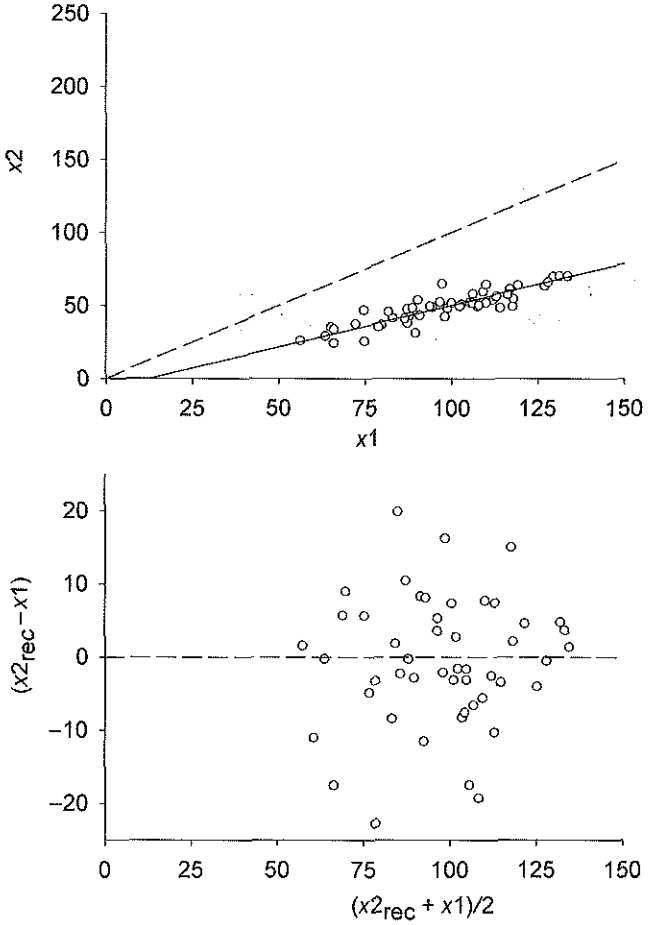

Figure 14-33 Scatter plot *(top)* and recalibration difference plots *(bottom)* of $(x2_{rec} - x1)$ differences against $(x2_{rec} + x1)/2$ for situations corresponding to one simulation run of $N = 50$ ($x1$, $x2$) sets for the following parameter values: $\alpha_0 = 0$, $\beta = 0.5$, $\sigma_{x1} = 5$, and $\sigma_{x2} = 5$.

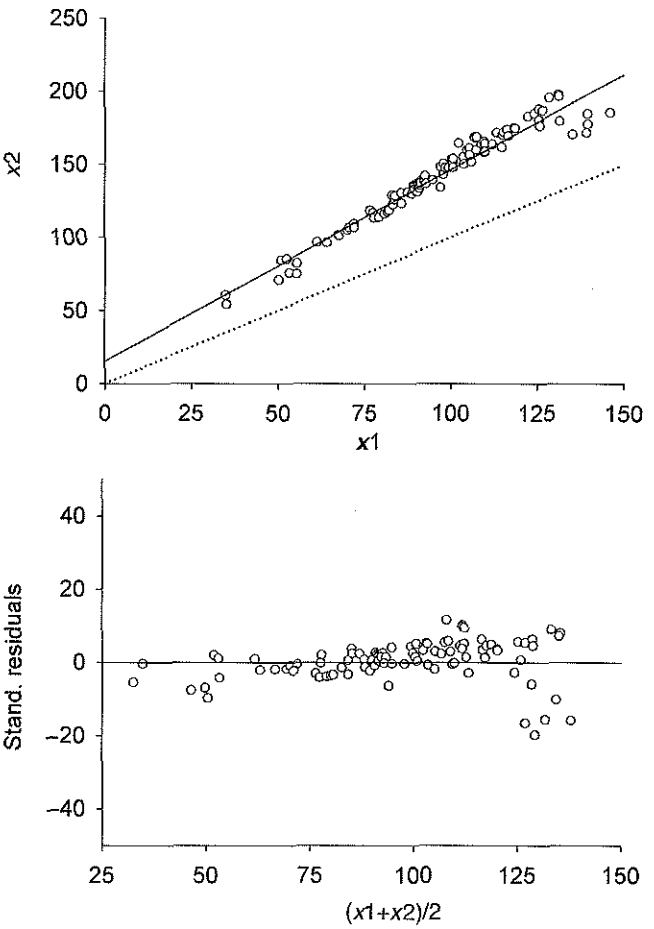

Figure 14-34 *Top,* Scatter plot showing an example of nonlinearity in the form of downward deviating $x2$ values at the upper part of the range. *Bottom,* Plot of residuals showing the effect of nonlinearity. At the upper end of the analytical measurement range, a sequence (run) of negative residuals is present from $x = 150$ to 200.

slope exceeding unity. The overall expression for the random error between the differences of $x1$ and $x2_{rec}$ becomes

$$\sigma_{(x2rec-x1)} = \left[(\sigma_{A2}/\beta)^2 + (\sigma_{RB2}/\beta)^2 + \sigma_{A1}^2 + \sigma_{RB1}^2\right]^{0.5}$$

In a real example, $\sigma_{(x2rec-x1)}$ is estimated from the set of paired differences between rescaled $x2$ values and $x1$ values and may be conveniently displayed in the form of a recalibration difference plot that also serves as a validation of the presumed linear relationship between the original sets of measurements. From the magnitude of the standard deviation of the paired differences, one may then judge whether it is acceptable to interchange measurements between method 1 and the rescaled method 2.

Testing for Linearity

Splitting of the systematic error into a constant and a proportional component depends on the assumption of linearity, which should be tested. A convenient test is a runs test, which in principle assesses whether the negative and positive deviations from the points to the line are randomly distributed over the analytical measurement range.[20] The term *run* here relates to a sequence of deviations with the same sign. Consider for example the situation with a downward trend of $x2$ values at the upper end of the analytical measurement range (Figure 14-34, *A*). The standardized deviations from the line (i.e., the residuals) will then tend to be negative in this area instead of being randomly distributed above and below the line[64] (Figure 14-34, *B*). Given a sufficient number of points, such a sequence will turn out to be statistically significant in a runs test.

Nonparametric Regression Analysis (Passing-Bablok)

The slope and intercept may be estimated by a nonparametric procedure, which is robust to outliers, and requires no assumptions of Gaussian error distributions.[82] Notice, however, that the parametric regression procedures do not presume Gaussian distributions of target values, but only of the error distributions. Furthermore, the jackknife principle used for estimation of standard errors for Deming and

weighted Deming procedures is also in principle nonparametric. Thus the main advantage of the nonparametric procedure is its robust performance in the presence of outliers. The method takes measurement errors for both $x1$ and $x2$ into account, but the method presumes that the ratio between analytical standard deviations is related to the slope in a fixed manner

$$\lambda = \left(SD_{RB1}^2 + SD_{A1}^2\right)/\left(SD_{RB2}^2 + SD_{A2}^2\right) = 1/\beta^2$$

Otherwise, a biased slope estimate is obtained.[66,83] The procedure may be applied both in situations with constant analytical standard deviations and in cases with proportional analytical standard deviations. The method is not as efficient as the corresponding parametric procedures (i.e., Deming and weighted Deming procedures).[66]

Slope and intercept with CIs are provided together with Spearman's rank correlation coefficient. A software program is required for the procedure.

Principle of Computations

The procedure consists of calculating all sets of possible slopes from the set of $N(x1, x2)$ values

$$S_{ij} = (x2_i - x2_j)/(x1_i - x1_j) \text{ for } 1 \le i < j \le N$$

The slope is in principle obtained as a shifted median

$$b = S_{((n+1)/2+K)} \text{ for odd } n$$

$$b = \exp((\log(S_{(n/2+K)}) + \log(S_{(n/2+1+K)}))/2) \text{ for even } n \text{ (geometric mean)}$$

where n is the total number of S_{ij} values, and K is the number of S_{ij} values below -1.

The intercept a_0 is obtained as the median of all $(x2_i - bx1_i)$.

CIs for slope and intercept are derived as described.[82] No standard error is obtained in this purely nonparametric procedure. If the CI for the slope does not include 1, the deviation is statistically significant and analogous for the intercept.

Interpretation of Systematic Differences between Methods Obtained on the Basis of Regression Analysis

A systematic difference between two methods is identified, if the estimated intercept differs significantly from zero, or if the slope deviates significantly from 1. This is decided on the basis of t-tests

$$t = (a_0 - 0)/SE(a_0)$$

$$t = (b - 1)/SE(b)$$

$SE(a_0)$ and $SE(b)$ are the standard errors of the estimated intercept a_0 and slope b, respectively. For OLR and WLR, the standard errors are calculated from the formulas presented previously. These formulas also apply approximately for the Deming and weighted Deming procedures. An exact procedure is to apply a computerized resampling principle called the jackknife procedure, which in practice can be carried out using appropriate software[69] (described on the book's accompanying Evolve site).

Having estimated a_0 and b, we have the estimate of the systematic difference between the methods, D_c, at a selected concentration $X1'_{Targetc}$

$$D_c = X2'_{Targetestc} - X1'_{Targetc} = a_0 + (b - 1)X1'_{Targetc}$$

$X2'_{Targetestc}$ is the estimated $X2'$ target value at $X1'_c$. Notice that D_c refers to the *systematic* difference (i.e., the difference between target values), and so it is not a total error including random measurement errors.

The standard error of the estimated systematic difference D_c should be considered. For OLR the formula applies

$$SE(D_c) = SD_{21}\left[1/N + (X1'_{Targetc} - x_m)^2/u\right]^{0.5}$$

For WLR we have the analogous formula

$$SE(D_c) = k_{21}\left[1/\sum w_i + (X1'_{Targetc} - x_{mw})^2/u_w\right]^{0.5}$$

where $k_{21} = [\Sigma(x2_i - X2'_{Targetesti})^2 w_i/(N-2)]^{0.5}$. The formulas given above for OLR and WLR apply approximately for Deming and weighted Deming regression, respectively. An exact procedure is to apply the jackknife procedure using a software program.[69] By evaluating the standard error throughout the analytical measurement range, a confidence region for the estimated line can be displayed (see Figure 14-30). It is apparent from the structure of the formulas that the confidence region is narrowest at the center of the range (x_m or x_{mw}). If method comparison is performed to assess the ability to trace, correction of a significant systematic difference D_c will often be performed by recalibration ($x2_{rec} = (x1 - a_0)/b$)). The associated standard uncertainty is the standard error of D_c (see section on Traceability). Even though the intercept and slope are not significantly different from zero and one, respectively, the combined expression D_c may be significantly different from zero. This may occur in situations in which the intercept and slope deviations are in the same direction.

Example of Application of Regression Analysis (Weighted Deming Analysis)

Application of weighted Deming regression analysis may be illustrated by the comparison of drug assays example ($N = 65(x1, x2)$ measurements). As outlined in detail previously, in this example the random error of the differences increases with the concentration, suggesting that the weighted form of Deming regression analysis is appropriate. Figure 14-35 shows (A) the estimated regression line with 95% confidence bands and (B) a plot of residuals. The nearly homogeneous scatter in the residuals plot supports the assumed proportional random error model and the assumption of linearity. The slope estimate (1.014) is not significantly different from 1 (95% CI: 0.97 to 1.06), and the intercept is not significantly different from zero (95% CI −6.7 to 47.4) (Table 14-12). A runs test for linearity does not contradict the assumption of linearity. The amount of random error is

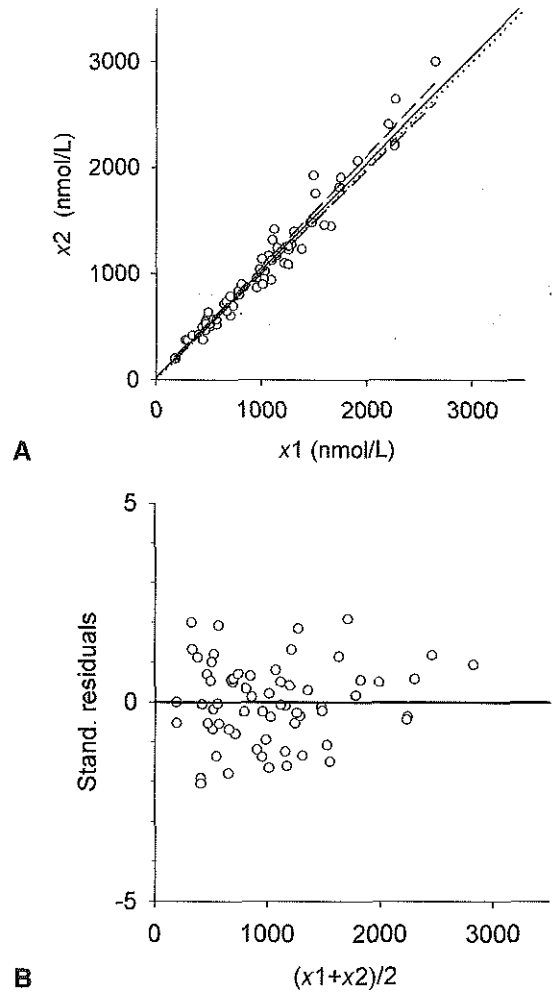

Figure 14-35 An example of weighted Deming regression analysis for the comparison of drug assays. **A,** The solid line is the estimated weighted Deming regression line, the dashed curves indicate the 95% confidence region, and the dotted line is the line of identity. **B,** A plot of residuals standardized to unit standard deviation. The homogeneous scatter supports the assumed proportional error model and the assumption of linearity.

quantified in the form of the SD_{21} proportionality factor equal to 0.11 or 11%. In the present example with a slope close to unity and two field methods with assumed random errors of about the same magnitude we divide the random error by the square root of two and get $CV_{x1} = CV_{x2} = 7.8\%$. In this simple case with a slope of unity, the results correspond to those previously derived in the analysis of the distribution of relative differences. Quality control data in the laboratory have provided CV_As of 6.1% and 7.2% for method 1 and 2, respectively. Thus in this example the random error largely may be attributed to analytical error. The assay principle is for both methods HPLC, which generally is a rather specific measurement principle, and considerable random bias effects are not expected in this case. If one or both of the assays had been immunoassays, the situation might have been different.

In the table, the estimated systematic differences at the limits of the therapeutic interval (300 and 2000 nmol/L) are displayed (24.6 and 48.9 nmol/L, respectively). This corresponds to percentage values of 8.2% and 2.4%, respectively. The estimated standard errors by the jackknife procedure yield the 95% CIs as shown in the table. At the low concentration, the difference is significant (95% CI: 5.7 to 44 nmol/L does not include zero), which is not the case at the high level (95% CI: −19 to 117 nmol/L). Even though the intercept and slope estimates separately are not significantly different from the null hypothesis values of zero and 1, respectively, the combined difference $Delta_c$ is significant at low concentrations in this example. If the difference is considered of medical importance and both methods are to be used simultaneously in the laboratory, a recalibration of one of the methods might be considered.

Estimating Sample Size Necessary for Method Comparison Studies

In the planning phase of a method comparison study, one should consider the size of the medically significant difference or critical difference Δ_c that should be detected at a given concentration $X1'_{\text{target}c}$ (see *Analytical Goals*)

TABLE 14-12 Results of Weighted Deming Regression Analysis for the Comparison of Drug Assays Example, $N = 65$ ($x1$, $x2$) Measurements

	Estimate	SE	95%-CI
Slope (b)	1.014	0.022	0.97 to 1.06
Intercept (a_0)	20.3	13.5	−6.7 to 47.4
Weighted correlation coefficient	0.98		
SD_{21} proportionality factor	0.11		
Runs test for linearity	n.s.		
$Delta_c = X_2 - X_1$ at $X_c = 300$	24.6	9.5	5.72 to 43.6
$Delta_c = X_2 - X_1$ at $X_c = 2000$	48.9	34.2	−19.3 to 117

(Figure 14-36). One may then derive the requirements for detecting critical sizes of α_0 and slope deviation from unity $(\beta - 1)$:

$$\Delta_c = X2'_{\text{Target}c} - X1'_{\text{Target}c} = \alpha_0 + (\beta - 1)X1'_{\text{Target}c}$$

In the following section, statistical power considerations with regard to testing for intercept and slope deviations are presented.

Statistical Power Considerations in Method Comparison Studies

The investigator should consider whether the study design is likely to disclose critical differences of clinical relevance. Important factors in this context are the range of measurements, the SDs of the random errors of the involved methods, and the number of samples. These factors determine the statistical power of a method comparison study (i.e., the ability of the data analysis procedure to verify the presence of a given systematic difference).

Having decided from above what values of α_0 and $(\beta - 1)$ should be detected, the next step is to design the method comparison study appropriately. First, a relevant range of values should be included (i.e., covering the range of clinical interest). A uniform distribution of values over the range is preferable and is primarily supposed in the present evaluation. Secondly, we have to consider the random errors of the methods. Two situations should be considered: the presence of constant and variable SDs for random error. The first possibility is mainly of interest given a short range of measured concentrations (e.g., in case of electrolyte methods). Given ranges of more than 1 or more decades, the standard deviations of the random error distributions usually vary with the measured concentration, often in a roughly proportional way.[93] Finally, specific values for the SDs or CVs of the methods should be assigned from available quality control data and assumptions concerning random matrix-related errors. According to the formula presented below and as explained in more detail,[69] we now have the necessary information to plan the comparison study (i.e., to decide on the necessary number of samples).

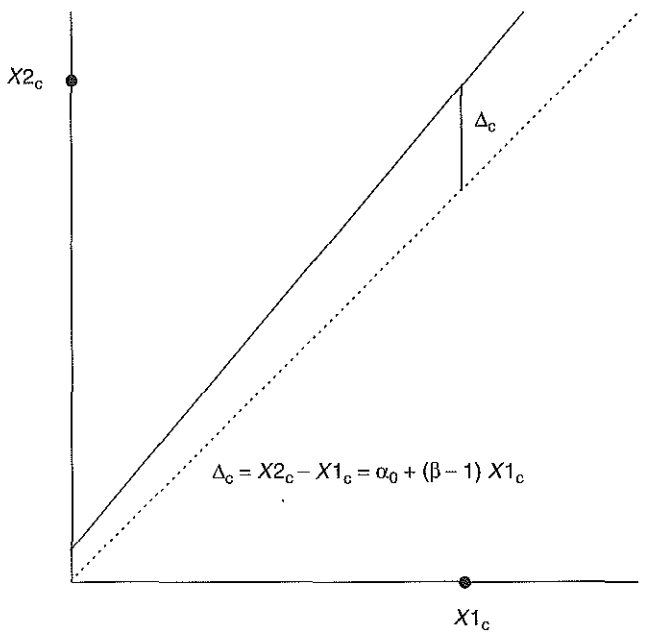

Figure 14-36 Illustration of the systematic difference Δ_c between two methods at a given level $X1_c$ according to the regression line. The difference is a result of a constant systematic difference (intercept deviation from zero) and a proportional systematic difference (slope deviation from unity). The dotted line represents the diagonal $X2 = X1$.

A general, simplified formula for approximating the sample size necessary for detection of a given deviation Δ of slope from unity or intercept from zero is[69]:

$$N = (c/\Delta)^2 (t_{p/2} + t_{1-q})^2$$

Δ is the actual difference in slope from unity (or intercept from zero), and c is a constant determining the standard error $(= c/\sqrt{N})$ of the *estimated* difference D corresponding to the true difference Δ. $t_{p/2}$ depends on the significance level p (Type I error) and is 1.96 (asymptotically) for p less than or equal to 5%. t_{1-q} reflects the statistical power $(1 - q)$, which is the probability of verifying a real difference Δ. The complement of statistical power is the Type II error (q), which is the probability of overlooking a real difference Δ. For a traditional power level of 90%, t_{1-q} takes the value 1.28. Finally the sample size is, in principle, inversely related to the squared difference Δ (i.e., if a given difference is halved, the sample size requirement is increased by a factor of four). At small to moderate sample sizes, however, adjustment of the t-value from the asymptotic value and the general impact of approximations disturb this relationship slightly.[69]

The relation between the null hypothesis situation of no difference (difference = 0) and the alternative hypothesis of the presence of a real difference (difference = Δ) is schematically shown in Figure 14-37. The figure outlines the hypothetical situation corresponding to a set of repeated method comparison studies that results in observed differences D that are distributed around the true difference, which is zero under the null hypothesis of no difference and equal to Δ under the alternative hypothesis. The larger the sample size is, the narrower the dispersions of observed differences around the true values are. Thus for a given Δ and Type I error the power increases with the sample size.

The necessary sample sizes for a series of standard method comparison situations in clinical chemistry have been tabulated (Tables 14-13 and 14-14). A Type I error (significance level) of 5% and a power of 90% have been assumed. Table 14-13 concerns the situation with *constant* SDs over the analytical measurement range, and Table 14-14 covers cases with *proportional* SDs.

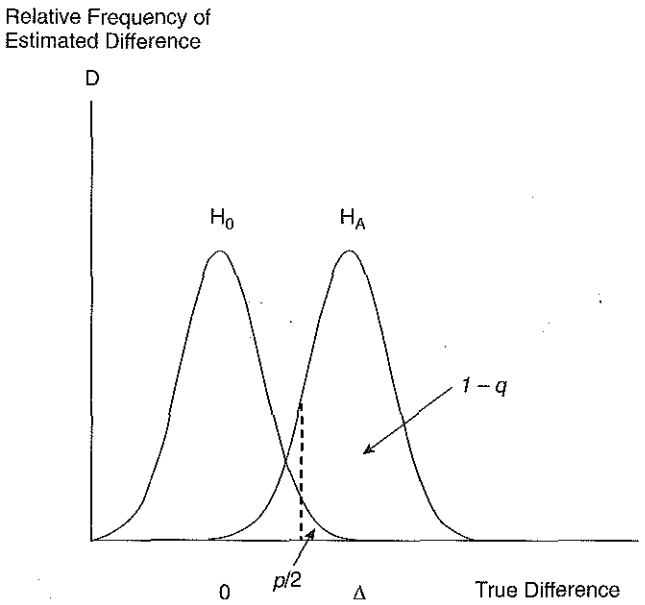

Figure 14-37 Schematic illustration of distributions of differences *D* under the null hypothesis (H_0) of no real difference and the alternative hypothesis (H_A) of the presence of a real difference Δ. The vertical dotted line indicates the limit of statistical significance. *p* is the Type I error (5%), and $1 - q$ is the power (90%). *(From Linnet K. Necessary sample size for method comparison studies based on regression analysis. Clin Chem 1999;45:882-94.)*

Power in Case of Constant Error Standard Deviations

Table 14-13 covers intervals with ratios from 1.25 to 10 for the maximum value divided by the minimum value (range ratio = maximum value/minimum value). The other entry in the table is the standardized delta value for slope or intercept. As regards the slope, this value refers to the slope deviation from unity measured in analytical coefficient of variation units:

$$\Delta\beta_{st} = (\beta - 1)/CV$$

where CV refers to $[CV_A^2 + CV_{RB}^2]^{0.5}$. Notice that the CVs (expressed as fractions) enter the formula, even though constant SDs are supposed, implying that the CVs are not constant over the analytical measurement range. The CVs in the formula refer to the specific CV value at the middle of the interval of interest (i.e., $CV = SD/x_m$), where x_m is the mean of the interval for the analytes.[69] It is assumed in the present context that the CV values for method 1 and 2 are identical. CV_A values may be known from quality control data. CV_{RB} values are usually not known. Depending on knowledge about the analytical principles and the likely influence of matrix effects a reasonable value should be assumed. In some situations, a value of zero is reasonable; in other cases a value similar to the CV_A might be assumed.

With regard to the intercept deviation from zero, the standardized delta value is:

$$\Delta\alpha_{0st} = (\alpha_0 - 0)/SD$$

TABLE 14-13 Sample Size Table for Comparison of Methods With *Constant* Standard Deviations for Random Errors Using Deming Regression Analysis*

Necessary sample sizes for test of slope deviation from 1 or intercept deviation from zero by Deming regression analysis given constant error standard deviations: $SD_{x1} = SD_{x2} = SD$. Uniform $x1$ and $x2$ distributions on intervals with the given range ratio. The range ratio is the maximum value divided by the minimum value of the considered interval.

OLR (given no random error in $x1$) requires half the listed sample sizes.

*From Linnet K. Necessary sample size for method comparison studies based on regression analysis. Clin Chem 1999;45:882-94.

†CV refers to the coefficient of variation for the random error at the middle of the given interval (SD/x_m).

where SD refers to $[SD_A^2 + SD_{RB}^2]^{0.5}$. The standard situations presuppose that the analyte values are uniformly distributed over the intervals of interest. The table has only selected entry values. With regard to standardized deviations that are not covered, an approximate sample size may be obtained by interpolation or extrapolation. At large sample sizes, squared interpolation or extrapolation is reasonable (examples of squared interpolation and extrapolation are given in the example below), but for small sample sizes this relationship is not exactly valid. Concerning the tabulated range ratios, approximate interpolations can also be carried out. Estimation of N given assumptions not covered in the table may be performed on the basis of formulas as described.[69] Moreover, it may be prudent to add additional samples to take nonideal conditions into account (e.g., target value distributions that are not exactly uniform over the given interval) (see later). The tabulated values refer to application of Deming regression analysis assuming equal random errors for both methods. If OLR is applied and there are no random errors associated with the $x1$ values, the required sample sizes are half the tabulated values.

It is apparent from the table that the range of values is very important with regard to the required sample size for detection of a given standardized slope or intercept deviation. For very short ranges characteristic for electrolyte measurement methods, detection of a standardized slope or intercept deviation equal to 1 may require more than 1000 samples. On the other hand, the sample size requirements may be rather modest for analytes with values dispersed over wider ranges. As regards standardized deviations that are not covered, the approximate sample size may be obtained by squared interpolation or extrapolation

Example: Planning a Comparison of Two Potassium Methods (Constant SDs)

We first decide on the critical differences that should be detected. For convenience, we take as a basis the CLIA '88 demand, which amounts to 0.5 mmol/L throughout the analytical measurement range. Notice that CLIA '88 demands relate to the total error in relation to a target value of a quality control sample:

$$\text{Total Error} = \text{systematic error} + 1.65\,SD_A$$

The factor 1.65 corresponds to a total error assuming that 95% of the measurements are within the given limit.

We consider here decision levels of 3 and 6 mmol/L and suppose in the present example that the SD_A is 0.09 mmol/L, which corresponds to a CV_A of 2% at the mean (4.5 mmol/L) of the considered range. In the present example we set the random bias component to zero. Thus the systematic difference that should be detected is:

$$\Delta_c = 0.5\,\text{mmol/L} - 1.65 \times 0.09\,\text{mmol/L} = 0.35\,\text{mmol/L}$$

TABLE 14-14 Sample Size Table for Comparison of Methods With *Proportional* Standard Deviations for Random Errors Using Weighted Deming Regression Analysis*

Necessary sample sizes for test of slope deviation from 1 or intercept deviation from zero by weighted Deming regression analysis given proportional SDs (i.e., constant coefficients of variation): $CV_{x1} = CV_{x2} = CV$. Uniform distributions of $x1$ and $x2$ on intervals with the given range ratio. The range ratio is the maximum value divided by the minimum value of the considered interval.

WLR analysis (given no random error in $x1$) requires approximately half the listed sample sizes.

Type I error: 5%; Power: 90%.

†x_m is the midpoint of the actual interval of interest (e.g., x_m equals 6 for the interval [4; 8]), which has a range ratio of 2.

From the general formula:

$$\Delta_c = X2'_{\text{Target}c} - X1'_{\text{Target}c} = \alpha_0 + (\beta - 1)X1'_{\text{Target}c}$$

we obtain at $X1'_{\text{Target}c} = 3$ mmol/L:

$$0.35 = 3.35 - 3 = \alpha_0 + (\beta - 1)3$$

This corresponds to a requirement for detecting α_0 equal to ±0.35 mmol/L, if the systematic difference is ascribed to an intercept deviation. Relating the systematic difference to a slope deviation results in a demand of detecting $\beta = 1.12$ (3.35/3) or 0.88. Similarly, at the upper decision level of $X1'_{\text{Target}c} = 6$ mmol/L, we have again the limits ±0.35 mmol/L for detection of α_0, but now the demand for detecting a slope deviation has been sharpened to $\beta = 1.06$ (6.35/6) or 0.94.

We may now consider the various factors in the estimation of sample size. The first factor to consider is the analytical measurement range: 3 to 6 mmol/L (i.e., a range ratio of 2). We suppose as mentioned above that both methods have constant SDs corresponding to a CV% of 2% at the middle of the range (i.e., 0.09 mmol/L). We are now able to convert the slope delta value to a standardized value:

$$\Delta\beta_{st} = (\beta - 1)/\text{CV} = 0.06/0.02 = 3.0$$

Deming regression analysis is performed with a significance level (Type I error) of 5% and a statistical power of 90%. To get the necessary sample size, we consult Table 14-13 and look under a range ratio of 2 and a standardized slope deviation of 3 and find the sample size $N = 70$.

Table 14-13 also covers cases studied by the use of OLR. Under the given assumptions, the approximate sample size requirement for OLR is obtained by dividing the numbers by 2 (i.e., $N = 35$ in this case) (see the accompanying Evolve site). However, a correct statistical analysis based on OLR requires that the $x1$ method is without analytical errors.

For the intercept, we want to detect a deviation of ±0.35 mmol/L, which may be converted to:

$$\Delta\alpha_{0st} = (\alpha_0 - 0)/\text{SD} = 0.35/0.09 = 3.9$$

According to Table 14-13 the sample size requirement is $N = 40$ for a standardized deviation 4. By squared interpolation, we obtain $N = 42$ ($= 40 \times (4/3.9)^2$). Thus in this example the sample size requirement with regard to testing for intercept deviation from zero is less demanding than that of testing for a critical slope deviation.

Power in Case of Proportional Error Standard Deviations

Table 14-14 covers application of weighted Deming regression analysis in situations with *proportional* SDs (constant CVs) and includes intervals with range ratios extending from 2 to 100. The standardized slope deviation is here:

$$\Delta\beta_{st} = (\beta - 1)/\text{CV}$$

and the standardized intercept deviation from zero is:

$$\Delta\alpha_{0st} = (\alpha_0 - 0)/(\text{CV} \times x_m)$$

CV refers to $[\text{CV}_A^2 + \text{CV}_{RB}^2]^{0.5}$ and should be expressed as a fraction, not a percentage. x_m is the midpoint of the interval of interest. Application of Table 14-14 presupposes that the analytical methods have identical CVs, and that the analyte concentrations are uniformly distributed over the intervals of interest. The CV refers to single or duplicate sets of measurements as appropriate. Approximate sample sizes for application of WLR, assuming CV = 0 for method 1, are derived by division of the sample size values by 2.

With regard to testing slope deviations, the strong impact on sample size of the range of values is apparent. The required number of samples is of the same order of magnitude as for analogous situations with constant SDs. For example, detection of one standardized slope deviation with the given Type I error and power requires more than 500 samples when the range ratio is 2, but only 37 samples for a range ratio of 50 or higher. Below, the sample size requirement is considered for a comparison of two glucose methods with proportional SDs.

Example: Planning a Comparison of Two Glucose Methods (Proportional SDs)

We first decide on the critical differences that should be detected. For convenience, we apply CLIA '88 requirements, which specify that $\Delta = 10\%$ or 60 mg/L at low concentrations. We consider a decision level corresponding to a fasting plasma glucose concentration of 1260 mg/L, which is of relevance for the diagnosis of diabetes. Again we notice that CLIA '88 requirements relate to the total error. Assuming proportional SD_As with a CV_A of 3% for both methods and CV_{RB} equal to zero, we obtain the critical systematic difference as:

$$\Delta_c = 10\% - 1.65 \times 3\% = 5\%$$

We have:

$$\Delta_c = X2'_{\text{Target}c} - X1'_{\text{Target}c} = \alpha_0 + (\beta - 1)X1'_{\text{Target}c}$$

which corresponds to:

$$(0.05 \times 1260) = X2'_{\text{Target}c} - 1260 = \alpha_0 + (\beta - 1) \times 1260$$
$$\text{or } 63 = 1323 - 1260 = \alpha_0 + (\beta - 1) \times 1260$$

This relation translates to a requirement of detecting α_0 equal to ±63 mg/L, if the systematic difference is related to an intercept deviation. Ascribing the systematic difference to a slope deviation requires detecting $\beta = 1.05$ or 0.95.

Let us now consider the conditions: an analytical measurement range of 600 mg/L to 3000 mg/L (i.e., a range ratio of 5); the midpoint of the interval (x_m) = 1800 mg/L; and for both methods, proportional SD_As with CV_As = 0.03. The regression procedure is weighted Deming regression analysis with a significance level (Type I error) of 5% and a statistical power of 90%.

We standardize the slope deviation:

$$\Delta\beta_{st} = (\beta - 1)/\text{CV} = 0.05/0.03 = 1.7$$

From the column corresponding to a range ratio of 5 in Table 14-14, we find the required sample size to be between 114 and 33 measurements by each method. Squared interpolation gives $N = 46$ $(= 33 \times (2/1.7)^2)$. For WLR assuming $CV_A = 0$ for method 1, approximately half the number of samples are required ($N = 23$).

Concerning the intercept, we want to detect a deviation of ±63 mg/L, which may be converted to:

$$\Delta\alpha_{0st} = (\alpha_0 - 0)/(CV_A \times x_m) = 63/(0.03 \times 1800) = 1.2$$

From Table 14-14 we obtain $N = 48$ $(= 69 \times (1/1.2)^2)$ (i.e., in this case about the same number as that obtained for testing the critical slope deviation).

Other decision levels might also be considered (e.g., the nonfasting plasma glucose concentration limit of 2000 mg/L). In this proportional error model, the standardized slope deviation to be detected is the same at all decision levels, but the requirement for intercept detection varies with the concentration, so that the most demanding situations occur at low concentrations.

Discussion of Application of Regression Analysis

Most published method evaluations fail to apply regression analysis in a rigorous fashion. This section considers both the use of OLR instead of Deming regression and the use of unweighted analysis in the setting of proportional random errors.

Application of OLR in Case of Random Errors Associated with Both *x*1 and *x*2

OLR is the most widely used regression analysis procedure in method comparison studies. Thus it is important to consider the significance of the lack of consideration of measurement errors in $x1$ as outlined previously (see Figures 14-23 and 14-24). The bias problem concerning the slope is most significant when dealing with narrow measurement ranges (e.g., when comparing electrolyte measurements). It has been recommended that OLR may be applied when the correlation coefficient exceeds 0.975 or 0.99.[81] The correlation coefficient, however, also depends on the random error of $x2$, which has no influence on the bias problem. The bias of the slope estimate has as a consequence that the Type I error for the statistical analysis increases (i.e., the null hypothesis is rejected too frequently). Depending upon the range of test concentrations considered and the amount of random error associated with $x1$, this increase may be several fold higher than the nominal level of 5%. If the range of $X1'$ target values is large (e.g., corresponding to several decades), the problem is negligible.

Application of Unweighted Forms of Regression Analysis in Case of Proportional Random Errors

According to current practice in method comparison studies, it is usual to apply unweighted forms of regression analysis (i.e., OLR and the Deming procedure), even though the SDs vary with the measured concentration, as occurs with a proportional relation (constant CV_A). Thus it is of interest to consider what happens in these situations.[66]

Basically, OLR provides unbiased estimates of slope and intercept, if $x1$ is without random error, irrespective of whether the SD for random error of $x2$ is constant or varies with the measured concentration. In the same way, the Deming procedure provides unbiased estimates of slope and intercept, when the SDs vary, provided that their ratio is constant throughout the analytical measurement range. This aspect is important and means that generally the estimates of slope and intercept are reliable in this frequently encountered situation. However, additional aspects must be considered: the reliability of the associated statistical analysis and the efficiency of the unweighted estimation procedures. The presence of a proportional SD_A for the $x2$ measurements tends to independently increase the Type I error for the test of slope deviation using the OLR procedure, because the standard error of the slope is underestimated. The phenomenon is most pronounced for skew target value distributions, in which cases the Type I error may increase threefold to fourfold, becoming 15% to 20% compared with the nominal level of 5%.[66] For uniform and Gaussian target value distributions, the increase is up to 7.5% and 10%, respectively. Finally the precision of slope and intercept estimations is lower than that of WLR in case of a proportional SD_A for $x2$ measurements. For a range ratio of 10, 2.3 times as many observations are required for estimation of the slope with a given precision compared with the WLR procedure (Table 14-15). For the intercept, the factor is 3.9.

The major problem associated with application of the unweighted Deming analysis in case of proportional SD_As is the suboptimality of the unweighted approach (Table 14-15). For uniform distributions with range ratios from 2 to 100, 1.2 to 3.7 times as many samples are necessary to obtain the same precision of the slope estimate by the unweighted compared with the weighted approach. Thus the larger the range ratio, the more inefficient the unweighted method. If one intends to apply the unweighted Deming procedure in a situation with proportional SD_As, the sample size values of Table 14-14 should be multiplied by the adjustment factors that may be derived from Table 14-15.

In conclusion, planning a method comparison study to achieve a given power for detection of medically notable differences should be considered. In this way, a method comparison study is likely to be conclusive: either the null hypothesis of no difference is accepted, or the presence of a relevant difference is established. Otherwise, a statistically nonsignificant slope deviation from unity or intercept deviation from zero or both may either imply that the null hypothesis is true, or be an example of a Type II error (i.e., an overlooked real difference of medical importance).

Discussion of Method Comparison Approaches

The various approaches outlined above all have their merits and limitations. Much emphasis has been placed on the difference plot, usually in the form suggested by Bland and

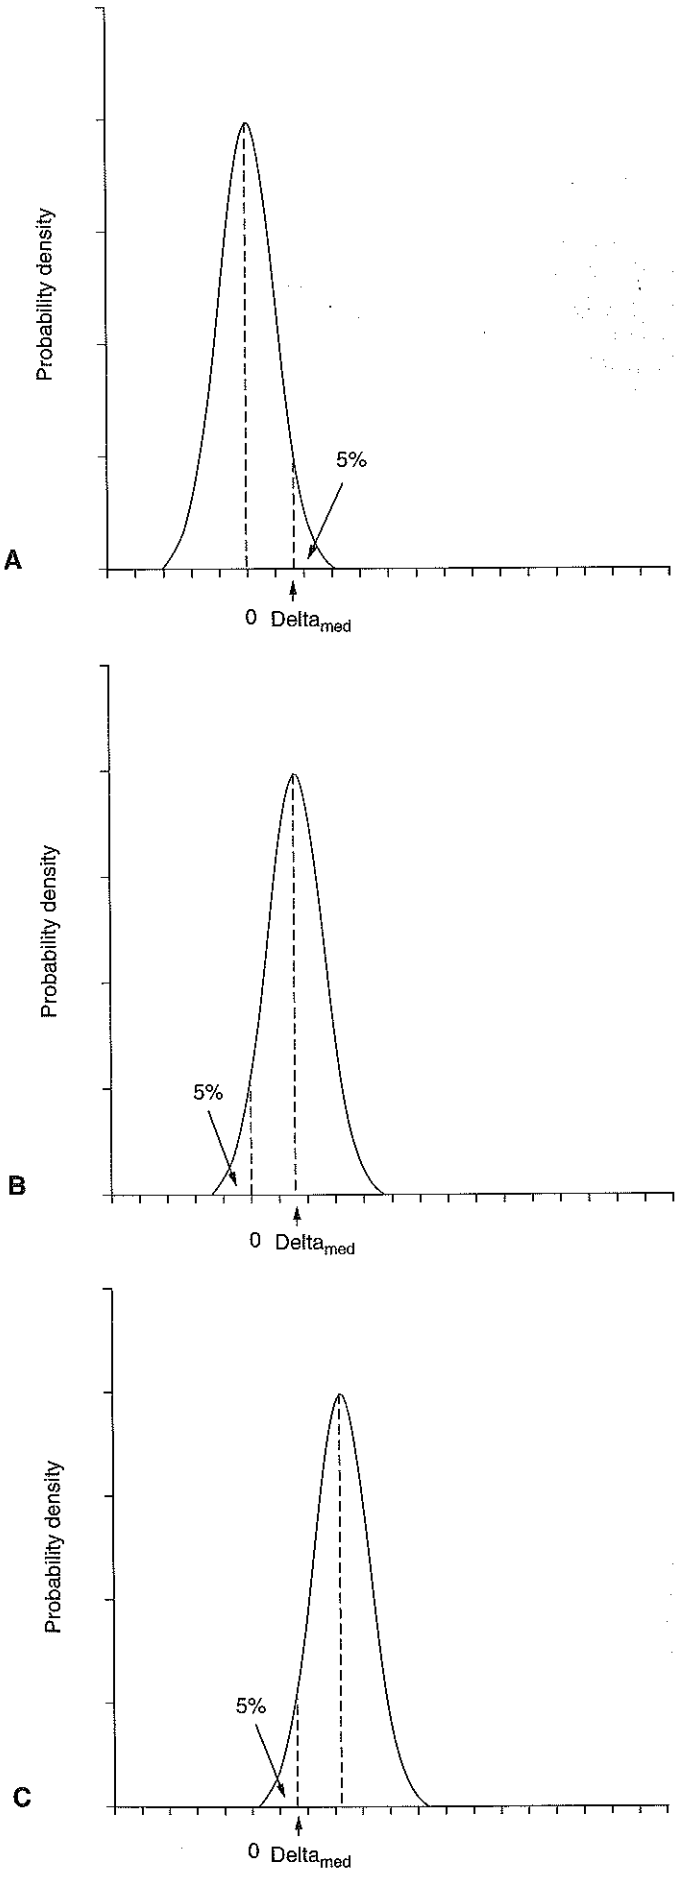
Altman.[4] Its advantage is that the differences are in focus and can be considered in detail. The *x-y* plot with a regression analysis line has been criticized for not displaying the differences explicitly, which may constitute a point in favor of the difference plot. On the other hand, when the relation between target values (i.e., the mean bias at a given concentration) changes drastically from plus to minus or vice versa, the *x-y* plot with regression analysis displays the relations accurately. All in all, the use of both a difference plot and an *x-y* plot with the estimated regression line will provide a good outline of both the mean bias as a function of the concentration and the random differences. It is important to get estimates of relevant measures for mean bias and random differences as outlined above. The use of the correlation coefficient should be avoided, because the interpretation is complex, and the value does not express relevant error measures.

MONITORING SERIAL RESULTS

An important aspect in clinical chemistry is monitoring of disease or treatment (e.g., tumor markers in case of cancer or drug concentrations in case of therapeutic drug monitoring). To assess changes in a rational way, the various imprecision components have to be taken into account. Biological within-subject variation ($SD_{within\text{-}B}$), preanalytical variation (SD_{PA}), and analytical variation (SD_A) all have to be recognized. We assume in the following discussion that preanalytical variation is already included in the estimated within-subject variation SD, which often is the case. On this basis, using the principle of adding squared standard deviations (variances) a total SD (SD_T) can be estimated:

$$SD_T^2 = SD_{Within\text{-}B}^2 + SD_A^2$$

The limit for statistically significant changes then is: $k\sqrt{2}\ SD_T$, where k depends on the desired probability level. Considering a two-sided 5% level, k is 1.96. The corresponding one-sided factor is 1.65. If a higher probability level is desired, k should be increased.



Limits for statistically significant changes ($Delta_{stat}$) may be related to changes that are considered of medical importance by clinicians (i.e., action limits [$Delta_{med}$]).[96] We will here consider a one-sided situation, where an increase is of importance, and a 5% significance level is selected (i.e., $Delta_{stat} = 1.65\sqrt{2}\ SD_T = 1.65\ SD_{delta}$). Suppose as a starting point that the true change ($Delta_{true}$) for a patient is zero (Figure 14-38, *A*). If $Delta_{stat}$ is less than $Delta_{med}$, the frequency of false-positive alarms will be less than 5%. If, on the other hand, $Delta_{stat}$ exceeds $Delta_{med}$, the frequency of false-positive alarms will exceed 5% (i.e., medical action will be taken too frequently). Figure 14-38, *A* illustrates the situation with $Delta_{stat}$ equal to $Delta_{med}$. We now consider the situation with a true change equal to the medically important change (i.e., $Delta_{true} = Delta_{med}$) (Figure 14-38, *B*), where exactly 50% of the observed changes exceed the medically important limit. If $Delta_{stat}$ is less than or equal to $Delta_{med}$, less than 5% of the patients will exhibit an observed delta value in the opposite direction of the true change (an obviously misleading trend). If the condition is not met, more than 5% will have a misleading change. Finally, in the case in which the true change equals the sum of $Delta_{med}$ and $Delta_{stat}$ (Figure 14-38, *C*) more than 95% of the observed changes exceed the medically important change and appropriate action will be taken for most patients.

The outline presented above illustrates that in the monitoring situation not only the requirement for statistical significance (i.e., the Type I error problem concerning false alarms), but also the Type II error problem or the risk of overlooking changes should be addressed; the latter is an aspect that often is overlooked.[63] Provided that $Delta_{stat}$ is small relative to $Delta_{med}$, both the Type I and II errors can be kept small. On the other hand, if $Delta_{stat}$ equals or exceeds $Delta_{med}$, the relative importance of Type I and II errors may be weighed against each other. If the consequences of overlooking a medically important change are serious, one should keep the Type II error small and accept a relatively large Type I error (i.e., accept the occurrence of false alarms). On the contrary, if overlooking changes only gives rise to minor or transient problems, the priority may be to keep the Type I error small. In addition to the simple evaluation of a shift between two measurements as considered here, sequen-

TABLE 14-15 Comparison of Sample Sizes Providing the Same Precision of Slope and Intercept Estimates by Unweighted and Weighted Deming Regression Analysis in Situations With Proportional Error SDs
Uniform *x*1 and *x*2 distributions are supposed on intervals with the given range ratio.

	Range Ratios						
	2	**3**	**5**	**10**	**25**	**50**	**100**

tial results may also be analyzed using more refined time-series models.[32]

TRACEABILITY AND MEASUREMENT UNCERTAINTY

As outlined previously in the error model sections, laboratory results are likely to be influenced by systematic and random errors of various kinds. Obtaining agreement of measurements between laboratories or agreement over time in a given laboratory often can be problematic.

Traceability

To ensure reasonable agreement between measurements of field methods, the concept of traceability comes into focus. *Traceability* is based on an unbroken chain of comparisons of measurements leading to a known reference value (Figure 14-39). A hierarchical approach for tracing the values of routine clinical chemistry measurements to reference and definitive methods was proposed by Tietz[103] and has been adapted by the ISO. For well-established analytes, a hierarchy of methods exists with *a primary reference procedure* at the top, *secondary reference procedures* at an intermediate level, and finally *routine methods* at the bottom.[10,43,103] A primary reference procedure is a fully understood procedure of highest analytical quality with complete uncertainty budget given in SI units.[21,39] The results of the primary reference method are obtained without reference to a calibrator for the analyte to be measured. The primary reference procedure is used to assign values to *primary calibrators.* Subsequently the primary calibrator is applied in the calibration of secondary reference procedures. Secondary reference procedures are used to measure the analyte concentration in *secondary calibrators,* which typically have the same matrix as the samples that are to be measured by the routine procedures (e.g., human serum). Secondary calibrators are usually of high analytical quality and certified. Using cortisol as an example, the primary measurement procedure may consist of weighing of cortisol and a chemical analysis for impurities. A primary calibrator is then a cortisol preparation with stated mass fraction (purity) (e.g., 0.998 and a 95% CI of ±0.001). The secondary reference measurement procedure is an isotope-dilution gas chromatography-mass spectrometry method. After the secondary calibrator, we have a measurement procedure used for commercial preparation of reagents, calibrators, and analytical kits for routine use in clinical chemistry laboratories. *The selected measurement* procedure is calibrated with a primary or secondary calibrator, and is used for measurement of the quantity in the manufacturer's *working calibrator.* The latter is used to calibrate the company's *standing measurement procedure,* which is a method that has been val-

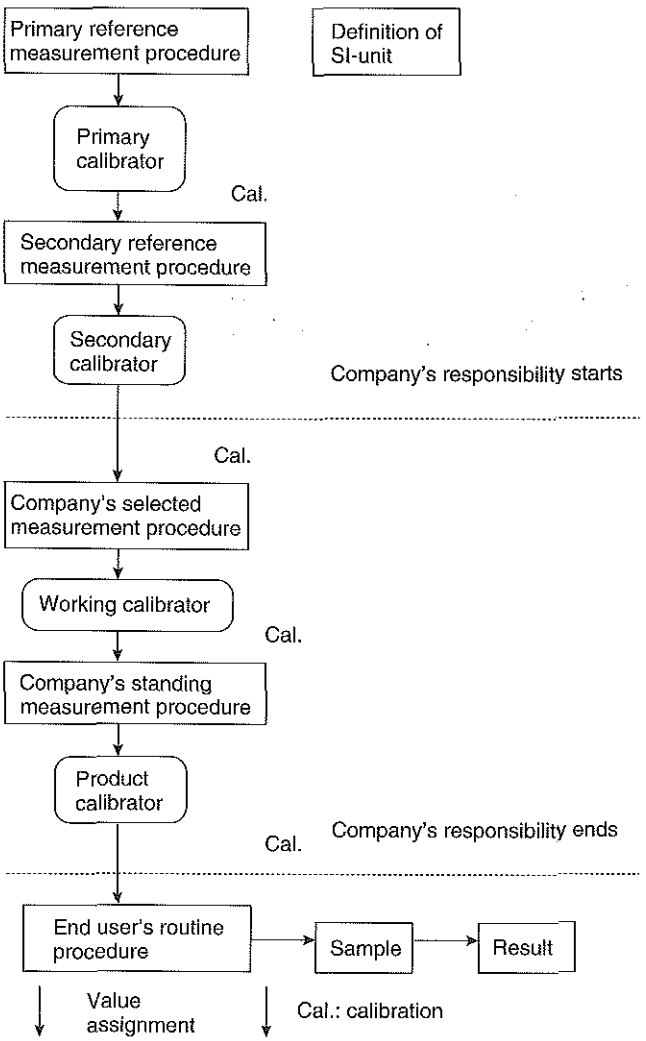

Figure 14-39 The calibration hierarchy from a primary method to a routine method. The uncertainty increases from top to bottom.

idated with regard to analytical specificity. The standing measurement procedure is applied for quantitation of the *product calibrator,* which is the calibrator for the routine method. The uncertainty of the measurement procedures increases from the top level to the bottom. Some recent ISO guidelines (15193 and 15194) address reference methods and reference materials.[39,40]

Only a minority (25 to 30) of clinical chemistry analytes are traceable to SI units (e.g., electrolytes), some metabolites (glucose, creatinine, and uric acid), steroid, and some thyroid hormones.[10,102] With protein hormones, the existence of heterogeneity or microheterogeneity complicates the problem of traceability.[102]

The Uncertainty Concept

To assess errors associated with laboratory results in a systematic way, the *uncertainty* concept has been introduced in laboratory medicine.[23,36] According to the ISO *Guide to the Expression of Uncertainty in Measurement* ("GUM"), *uncertainty* is formally defined as "a parameter associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be attributed to the measurand."[36] In practice, this means that the uncertainty is given as an interval around a reported laboratory result that specifies the location of the true value with a given probability (e.g., 95%). In general the uncertainty of a result, which is traceable to a particular reference, is the uncertainty of that reference together with the overall uncertainty of the traceability chain.[23] Updated information on traceability aspects is available on the website of the *Joint Committee on Traceability in Laboratory Medicine* (www.bipm.org/enus/2_Committees/JCTLM.shtml, Accessed August, 2003).

The Standard Uncertainty (u_{st})

The uncertainty concept is directed toward the end user (clinician) of the result, who is concerned about the total error possible, and who is not particularly interested in the question whether the errors are systematic or random. In the outline of the uncertainty concept it is assumed that any known systematic error components of a measurement method have been corrected, and the specified uncertainty includes the uncertainty associated with correction of the systematic error(s).[36] Although this appears logical, a problem may be that some routine methods have systematic errors dependent on the patient category from which the sample originates. For example, kinetic Jaffé methods for creatinine are subject to positive interference by alpha-keto compounds and to negative interference by bilirubin and its metabolites, which means that the direction of systematic error will be patient dependent and not generally predictable.

In the theory on uncertainty, a distinction between type A and B uncertainties is made. Type A uncertainties are frequency-based estimates of standard deviations (e.g., an SD of the imprecision). Type B uncertainties are uncertainty components for which frequency-based SDs are not available. Instead, the uncertainty is estimated by other approaches or by the opinion of experts. Finally the total uncertainty is derived from a combination of all sources of uncertainty. In this context, it is practical to operate with *standard uncertainties* (u_{st}), which are equivalent to standard deviations. By multiplication of a standard uncertainty with a *coverage factor* (k), the uncertainty corresponding to a specified probability level is derived. For example, multiplication with a coverage factor of two yields a probability level of $\approx$ 95% given a normal distribution. When considering the total uncertainty of an analytical result obtained by a routine method, the preanalytical variation, method imprecision, random matrix-related interferences, and uncertainty related to calibration and bias corrections (traceability) should be taken into account. Expressing the uncertainty components as standard uncertainties, we have the general relation:

$$u_{st} = \left[u^2_{PAst} + u^2_{Ast} + u^2_{RBst} + u^2_{Tracst}\right]$$

where the individual components refer to preanalytical, analytical, matrix-related random bias and traceability uncertainty.

Uncertainty can be assessed in various ways, and often a combination of procedures is necessary. In principle, uncertainty can be judged *directly* from measurement comparisons or *indirectly* from an analysis of individual error sources according to the law of error propagation ("error budget"). Measurement comparison may consist of a method comparison study with a reference method based on patient samples according to the principles outlined previously or by measurement of certified matrix reference materials (CRMs).

Example of Direct Assessment of Uncertainty on the Basis of Measurements of a Certified Reference Material

Suppose a CRM is available with a specified value 10.0 mmol/L and a standard uncertainty of 0.2 mmol/L. Ten repeated measurements in independent runs give a mean value of 10.3 mmol/L with SD 0.5 mmol/L. The standard error of the mean is then $0.5/\sqrt{10} = 0.16$ mmol/L. The mean is not significantly different from the assigned value ($t = (10.3 - 10.0)/(0.2^2 + 0.16^2)^{0.5} = 1.17$). The total standard uncertainty with regard to traceability is then $u_{\text{Tracst}} = [0.16^2 + 0.2^2]^{0.5} = 0.26$ mmol/L. If the bias had been significant, one might have considered making a correction to the method, and the standard uncertainty would then be the same at the given level. Thus the measurements of the CRM provide an estimate of the uncertainty related to traceability. The other components have to be estimated separately. Concerning method imprecision, the long-term imprecision (e.g., observed from quality control measurements) should be used rather than the short-term SD observed for the CRM material. We here suppose the long-term SD_A is 0.8 mmol/L. Data on preanalytical variation can be obtained by sampling in duplicates from a series of patients or can be a matter of judgment (type B uncertainty) from literature data or data on similar analytes. We here suppose SD_{PA} equals half the analytical SD (i.e., 0.4 mmol/L). Finally, we lack data on a possible random bias component, which we may choose to ignore in the present example. The standard uncertainty of the results then becomes:

$$u_{\text{st}} = \left[u_{\text{PAst}}^2 + u_{\text{Ast}}^2 + u_{\text{Tracst}}^2\right] = \left[0.4^2 + 0.8^2 + 0.26^2\right]^{0.5} = 0.93 \text{ (mmol/L)}$$

In this case, the major uncertainty component is the long-term imprecision in the laboratory.

Example of Direct Assessment of Uncertainty on the Basis of a Method Comparison Study with a Reference Method Using Patient Samples

Suppose a set of patient samples has been measured by a field method ($X2$) in parallel with a reference method ($X1$) and that a linear relationship exists between the measurements. We want to assess a possible bias and evaluate the standard uncertainty of the results of the field method on the basis of the regression analysis results and information on the standard uncertainty related to traceability of the reference method results. The imprecision of the reference method is assumed to be 2.5% or as a fraction (used in the following) 0.025 ($= CV_{A1}$), and the component relating to the uncertainty of the traceability chain for the reference method is 0.020 ($= u_{\text{Tracst}}$). Proportional measurement errors are assumed for both methods and a weighted form of Deming regression analysis is applied. The error variance ratio λ is not known exactly, but the reference method is devoid of random bias, so it is assumed that the random error level is about half that of the field method (i.e., λ is set to $1/2^2 = 1/4$). At a decision point ($X1'_{\text{Targetc}}$) (e.g., corresponding to the upper limit of the 95% reference interval), the systematic difference between the methods ($D_c = a_0 + (b - 1)\, X1'_{\text{Targetc}}$) is estimated with standard error (see regression section):

$$D_c = X2'_{\text{Targetc}} - X1'_{\text{Targetc}} = 20 \text{ mg/L with SE}(D_c) = 1.0 \text{ mg/L}$$

corresponding to a relative SE(D_c) of 0.050 ($= (1.0 \text{ mg/L})/(20 \text{ mg/L})$). For OLR analysis ignoring random measurement error with regard to $X1'_{\text{Targetc}}$, SE(D_c) can be computed as outlined in the regression section. For the Deming procedures, the standard error can be conveniently computed by the jackknife procedure (described on the book's accompanying Evolve site). We observe that the difference is highly significant and decide to recalibrate the field method in relation to the reference method using the estimated slope and intercept (i.e., the recalibrated $x2$ values equals $(x2 - a_0)/b$). Having done that, the field method is assumed to have no systematic error in relation to the reference method, but when considering the uncertainty of the results, we have to add the standard uncertainty of the bias correction. The uncertainty related to traceability for the field method is now obtained as the uncertainty inherent to the reference method and the comparison step, i.e.,

$$u_{\text{Tracst}} = \left[0.020^2 + 0.050^2\right]^{0.5} = 0.054$$

We are now further interested in deriving estimates of random error components for the field method from the regression analysis results. Both analytical error and random matrix-related error should be assessed, and it should be recognized that the observed total random error is the result of contributions from both measurement methods. Suppose that CV_{21} of the regression analysis has been calculated to be 0.10 (CV_{21} is analogous to SD_{21} or $SD_{y.x}$ given constant measurement errors over the analytical measurement range [i.e., an expression for the random error in the vertical direction in the x-y plot]). From the regression section, we have:

$$CV_{21}^2 = \left[CV_{A1}^2 + CV_{A2}^2\right] + \left[CV_{RB1}^2 + CV_{RB2}^2\right]$$

By substituting $CV_{A1} = 0.025$, $CV_{RB1} = 0$, and $CV_{21} = 0.10$, we derive

$$CV_{A2}^2 + CV_{RB2}^2 = 0.009375\ [CV_{A2}^2 + CV_{RB2}^2]^{0.5} = 0.0968$$

Thus the total random error of the field method corresponds to a CV of 0.097. If we had measured samples in duplicate in the method comparison experiment or had available quality control data, we could split the total random error into its components. CV_{A2} is here assumed to be 0.035, which gives a rest of 0.090 corresponding to CV_{RB2}. We may here notice that the assumed error ratio λ of $(½)^2$ is not quite correct. According to our results, λ should be $(0.025/0.0968)^2$. Although the Deming regression principle is rather robust toward misspecified λ values, we could choose to carry out a reanalysis with the more correct λ value, a process that could be iterated. Finally, assuming a value of 0.03 for the preanalytical coefficient of variation, we derive a total standard uncertainty estimate of:

$$u_{st} = [u_{PAst}^2 + u_{Ast}^2 + u_{RBst}^2 + u_{Tracst}^2]$$
$$= [0.03^2 + 0.0968^2 + 0.054^2]^{0.5} = 0.115$$

At the given decision level of 20 mg/L and with a coverage factor of 2, we obtain the 95% uncertainty interval of a single field measurement as:

$$20\,mg/L \pm (2 \times 0.115 \times 20)mg/L = 15.4 - 24.6\,mg/L$$

Having estimated the uncertainty as outlined, additional uncertainty sources should be considered. If the comparison was undertaken within a short time period, one might consider adding an additional long-term imprecision component as a variance component to the standard uncertainty expression.

When comparing the two approaches briefly outlined, the latter is the more informative. Using a series of patient samples instead of a pooled sample, individual random bias components are included in the uncertainty estimation, assuming the patient samples are representative. Also, natural patient samples are preferable to a stabilized pool that perhaps is distributed in freeze-dried form that may introduce artifactual errors in some analytical systems. Using a CRM, on the other hand, is more practical and in many situations the only realistic alternative.

With regard to uncertainty estimation from a comparison study of patient samples as outlined above, one should be careful concerning the uncertainty estimation. First, it is important to estimate correctly the standard error of the difference at selected decision points or at points covering the analytical measurement range (i.e., at the lower limit, in the middle part, and at the upper limit). From the expression of the estimated difference $(D_c = a_0 + (b - 1)\ X1'_{Targetc})$, one might at a first glance estimate the standard error (standard uncertainty) by adding (squared) the standard errors of the intercept and slope. However, simple squared addition of standard errors is only correct given independence of estimates (see below). Estimates of intercept and slope in regression analysis are negatively correlated, which implies that simple squared addition of standard errors leads to an overestimation of the total standard uncertainty.[16] Rather, a direct estimation procedure for the standard error should be applied as mentioned above.

A method comparison study based on genuine patient samples represents as mentioned a real assessment of traceability. In Figure 14-39, the focus is on the calibration aspect intended to *mediate* traceability. One should recognize that the matrix of product calibrators for practical reasons often is artificial (e.g., the matrix of a calibrator may be bovine albumin instead of human serum). Many routine methods are matrix sensitive, which implies that calibrators and patient samples are not commutable. To ensure traceability in this situation, the assigned concentration of a calibrator has to be different from the real concentration.

Uncertainty Estimation from External Quality Assessment Schemes

Measurement comparison with reference methods or measurement of CRMs may not be feasible. For example, measurement of newly detected biochemical markers may only be performed in a handful of research laboratories. In this case, collaborative studies or data from EQAS may constitute a source for uncertainty estimations. If the laboratory has performed repeated measurements over a time period, the standard deviation of differences (SD_{dif}) between the measured values and the consensus or assigned values may enter the uncertainty computations. If a significant systematic difference is observed, a correction should be considered. SD_{dif} can be considered as composed of the inherent (short-time) imprecision in the laboratory ($SD_{intralab}$) and a variability component reflecting variations over time of the systematic error (here expressed as SD_{ext}). For example, if an external control material is assayed monthly in duplicate and if the differences between the consensus values and the mean of duplicates are assessed, the following relation applies:

$$SD_{dif}^2 = SD_{ext}^2 + SD_{intralab}^2/2$$

Taking into account also the preanalytical variation associated with sampling and sample pre-treatment, the total standard uncertainty with traceability stated to the consensus mean is given by:

$$u_{st}^2 = SD_{PA}^2 + SD_{intralab}^2 + SD_{ext}^2$$

In case several laboratories use the same analytical reagent systems, a subgrouping of consensus means is often performed. When considering uncertainty, it should then be distinguished between traceability to the subgroup consensus and the overall consensus mean.

The total dispersion of values for a group of laboratories in an EQAS study for a given method gives an impression of the uncertainty level that can be achieved in practice. From the relation:

$$SD_{Total}^2 = SD_{intralab}^2 + SD_{interlab}^2$$

it is observed to what extent it is possible for groups of laboratories to conform to a common measurement level. Additional preanalytical uncertainty and uncertainty related to the traceability (bias) of the consensus mean should also be included. This total uncertainty expressed as a standard uncertainty can be used to consider the feasibility of using common decision levels (e.g., internationally agreed diagnostic or treatment limits).

Indirect Evaluation of Uncertainty by Quantification of Individual Error Source Components

On the basis of a detailed quantitative model of the analytical procedure, the standard approach is to assess the standard uncertainties associated with the individual input parameters and combine them according to the law of propagation of uncertainties.[23] The relationship between the combined standard uncertainty $u_c(y)$ of a value y and the uncertainty of the *independent* parameters $x_1, x_2, \ldots x_n$, on which it depends, is:

$$u_c[y(x_1,x_2,\ldots)] = \left[\sum c_i^2 u(x_i)^2\right]^{0.5}$$

where c_i is a sensitivity coefficient (the partial differential of y with respect to x_i). These sensitivity coefficients indicate how the value of y varies with changes in the input parameters x_i. If the variables are not independent, the relationship becomes:

$$u_c[y(x_i,x_k\ldots)] = \left[\sum c_i^2 u(x_i)^2 + \sum c_i c_k u(x_i,x_k)^2\right]^{0.5}$$

where $u(x_i, x_k)$ is the covariance between x_i and x_k, and c_i and c_k are the sensitivity coefficients. The covariance is related to the correlation coefficient ρ_{ik} by:

$$u(x_i,x_k) = u(x_i)u(x_k)\rho_{ik}$$

This is a complex relationship that usually will be difficult to evaluate in practice. In many situations, however, the contributing factors are independent, thus simplifying the picture. Below, some simple examples of combined expressions are shown. The rules are presented in the form of combining SDs or coefficients of variation (CVs) given *independent* input components.

$q = x + y$ $\quad \mathrm{SD}(q) = \left[\mathrm{SD}(x)^2 + \mathrm{SD}(y)^2\right]^{0.5}$

$q = x - y$ $\quad \mathrm{SD}(q) = \left[\mathrm{SD}(x)^2 + \mathrm{SD}(y)^2\right]^{0.5}$

$q = ax$ $\quad \mathrm{SD}(q) = a\,\mathrm{SD}(x)$ and $\mathrm{CV}(q) = \mathrm{CV}(x)$

$q = x^p$ $\quad \mathrm{CV}(q) = p^{0.5}\mathrm{CV}(x)$

$q = xy$ $\quad \mathrm{CV}(q) = \left[\mathrm{CV}(x)^2 + \mathrm{CV}(y)^2\right]^{0.5}$

$q = x/y$ $\quad \mathrm{CV}(q) = \left[\mathrm{CV}(x)^2 + \mathrm{CV}(y)^2\right]^{0.5}$

The formulas shown may be used, for example, to calculate the combined uncertainty of a calibrator solution from the uncertainties of the reference compound, the weighting, and dilution steps) (see below).

TABLE 14-16 Relations between Standard Deviation and Range for Various Types of Distributions

Normal Distribution	Rectangular Distribution	Triangular Distribution
SD = Half width of 95% interval/ $t_{0.975}(v)$ ≈ Half width of 95% interval/2	SD = Half width/$\sqrt{3}$	SD = Half width/$\sqrt{6}$

Some relations between the SD and nonnormal distributions may also be of relevance for uncertainty calculations (type B uncertainties) (Table 14-16). For example, if the uncertainty of a CRM value is given with some percentage, it may be understood as referring to a rectangular probability distribution. In relation to calibration of flasks, the triangular distribution is often assumed.

Example

Briefly, computation of the standard uncertainty of a calibrator solution will be outlined. The concentration C equals the mass M divided by the volume V ($C = M/V$). We will here express the standard uncertainties as relative values and derive the approximate total standard uncertainty by squared addition of the individual contributions. Starting with the mass, the purity is stated on the certificate as 99.4% ± 0.4%. Assuming a rectangular distribution, the relative standard deviation becomes $0.004/\sqrt{3} = 0.0023$. The uncertainty of the weighing process is known in the laboratory to have a CV of 0.1% or 0.0010. Thus the relative standard uncertainty of the mass becomes:

$$u_{\mathrm{Mst}} = \left[0.0023^2 + 0.0010^2\right]^{0.5} = 0.0025$$

The certificate of the flask (50 mL at 20 °C) indicates ±0.1 mL as uncertainty. Assuming here a triangular distribution, we derive the standard uncertainty as $0.10\,\mathrm{mL}/\sqrt{6} = 0.0408\,\mathrm{mL}$, which is converted to a relative value of 0.000816. The temperature expansion coefficient is given as 0.020 mL per degree change of temperature. Assuming a variability of 20 ± 4 °C, this contribution amounts to ±0.080 mL. Assuming here a rectangular distribution, we get an SD of $0.080/\sqrt{3}$ mL, or 0.00092 as a relative SD. The repeatability of the volume dispensing process in the laboratory has been assessed to 0.020 mL expressed as an SD, which corresponds to a relative value of 0.00040. The total standard uncertainty of the volume dispensing process becomes:

$$u_{\mathrm{Vst}} = \left[0.000816^2 + 0.00092^2 + 0.00040^2\right]^{0.5} = 0.0013$$

The total standard uncertainty of the calibrator solution is:

$$u_{Calst} = \left[u_{Mst}^2 + u_{Vst}^2\right]^{0.5} = 0.0025^2 + 0.0013^2$$
$$= 0.0028 \text{ or } 0.28\%$$

Quite generally, when adding squared CVs, minor contributions can in practice be ignored (e.g., CVs less than a third or quarter of the other components).[23]

The indirect procedure is mainly of relevance for relatively simple procedures. In some situations, a simulation model of a complex analytical method may be established to estimate the combined uncertainty of the method on the basis of the input uncertainties.[2] For closed, automated clinical chemistry procedures it will often not be possible to discern the individual error elements. Further, the correlation aspect is difficult to take into account in practice. In these cases, the direct procedure of measurement comparison is preferable. However, the indirect procedure has been applied in clinical chemistry.[59]

Uncertainty in Relation to the Traditional Systematic and Random Error Classifications

As mentioned above, systematic errors have no place in the uncertainty expression, because it is assumed that they have been corrected, so that it is the uncertainty of the correction procedure that should be taken into account. Otherwise, systematic errors have been added linearly or squared in error propagation models.[87,100] One may further consider that the distinction between systematic effects and random effects may be a matter of the reference frame. For example, a systematic error over time may turn into a random error, because a bias may change over time. Lot to lot reagent effects may be interpreted as either systematic or random errors. When a laboratory changes from an old to a new lot, a shift in measurement level may occur, which initially will be considered as a systematic change. However, over a long time period involving several lots of reagents, the recorded shifts will typically be up and down and be regarded as a long-term random error component. Additionally, a bias in a particular laboratory may be viewed as a random error component, when dealing with a whole group of laboratories, because the individual laboratory biases appear randomly distributed and are quantified as the interlaboratory standard deviation. Thus there are arguments for using the uncertainty concept as outlined above to end up with one overall uncertainty expression directed toward the end user of the laboratory result. Still, as mentioned previously, systematic errors linked to samples from specific patient subcategories may constitute a problem, because a general correction is not possible. A way to quantify this error contribution is to include samples from all patient subgroups in a balanced way in a method comparison study, so that this error type is incorporated in the uncertainty component related to traceability. Another problem with systematic errors is that they often depend on the analyte concentration. Thus if a CRM is measured at a particular concentration, one should consider whether a bias correction is valid only at the given level or generally over the analytical measurement range. Further, the occurrence of outliers caused by rarely occurring interference (e.g., heterophilic antibodies in relation to immunoassays) also constitutes a problem.[56] If the uncertainty estimation is based on parametric statistics (standard uncertainty expanded by a coverage factor), inclusion of gross outliers may increase the standard uncertainty considerably and make the uncertainty specification useless. A solution might here be to omit the outliers in the first hand, compute the 95% uncertainty interval, and then finally add a special note with regard to the probability of occurrence of outliers in the uncertainty specification.

Although it may appear complicated to specify the uncertainty in a detailed manner, a rough estimate may be obtained by adding the squares of CVs corresponding to essential uncertainty elements (e.g., grouped as the factors outside the laboratory) (derived from the traceability chain), the analytical factors inside the laboratory (intermediate precision), and the preanalytical elements.[49] In estimating uncertainty, it is important to include relevant elements, but be careful not to count the same elements twice. It should be recognized that the simple squared addition principle requires independence. Finally, because of the squared addition principle of CVs, minor contributions can in practice be ignored. The application of the uncertainty concept in the field of clinical chemistry is currently subject to some discussion.[50,56]

GUIDELINES, REGULATORY DEMANDS, AND ACCREDITATION

Various guidelines and regulatory demands are of relevance in relation to analytical methods used in clinical chemistry. Examples of the NCCLS guidelines have been referred to in the individual subsections and various ISO documents. Here some general guidelines will be mentioned briefly.

ISO15189 Medical Laboratories—Particular Requirements for Quality and Competence is a universal standard for quality management in medical laboratories that specifies requirements in general terms applicable to all medical laboratory fields.[42] The standard is intended to form the basis for accreditation of medical laboratories. In addition to general laboratory conditions in relation to quality control, the standard focuses on medical competence, interpretation of test results, selection of tests, reference intervals, ethical aspects, and safety. An annex concerns quality management of laboratory computer systems.

Concerning regulatory demands, the CLIA regulations in the United States have exerted a large influence on quality considerations in clinical chemistry[104,105] (see Table 14-5). From a manufacturer's perspective, the Food and Drug Administration (FDA) requirements for validation of new assays are of prime importance in the United States. In Europe, the *IVD-directive* (Directive 98/79 of the European

Community on In-Vitro Diagnostics) is a European legislative regulation directed at in vitro manufacturers.[18] The directive demands that the manufacturer have a quality management system and that products are validated by competent laboratories. It is required that the traceability of values assigned to calibrators or control materials or both must be ensured through available reference measurement procedures and/or available materials of higher order. Explicit statement of the uncertainty of calibrator values is not required, but indirectly the manufacturers have to address the uncertainty of the traceability chain to ensure traceability.

SOFTWARE PACKAGES

Statistical analyses are today usually carried out either in spreadsheets or by statistical programs. Concerning the latter, large general program packages may be applied or smaller programs more or less specialized toward the field of clinical chemistry. Various large general packages are on

BOX 14-1 Abbreviations and Vocabulary

Abbreviations

CI	Confidence interval
CV	Coefficient of variation (= SD/x, where x is the concentration)
CV%	= CV × 100%
CV_A	Analytical coefficient of variation
CV_{RB}	Random bias coefficient of variation
DoD	Distribution of differences (plot)
ISO	International Organization for Standardization
IUPAC	International Union of Pure and Applied Chemistry
OLR	Ordinary least-squares regression analysis
SD	Standard deviation
SD_A	Analytical standard deviation
SD_{RB}	Random bias standard deviation
SEM	Standard error of the mean (= SD/$\sqrt{N}$)
x_m	Mean
x_{mw}	Weighted mean
WLR	Weighted least-squares regression analysis

Vocabulary*

Analyte Compound that is measured.

Bias Difference between the average (strictly the expectation) of the test results and an accepted reference value (ISO 3534-1). Bias is a measure of trueness.[34]

Certified Reference Material (CRM) is a reference material, one or more of whose property values are certified by a technically valid procedure, accompanied by or traceable to a certificate or other documentation that is issued by a certifying body.

Commutability Ability of a material to yield the same results of measurements by a given set of measurement procedures.

Limit of Detection The lowest amount of analyte in a sample that can be detected but not quantified as an exact value. Also called lower limit of detection, minimum detectable concentration (or dose or value).[38]

Matrix All components of a material system, except the analyte.

Measurand The "quantity" that is actually measured (e.g., the concentration of the analyte). For example, if the analyte is glucose, the measurand is the concentration of glucose. For an enzyme, the measurand may be the enzyme *activity* or the *mass concentration* of enzyme.

Measuring interval Closed interval of possible values allowed by a measurement procedure and delimited by the *lower limit of determination* and the *higher limit of determination.* For this interval, the total error of the measurements is within specified limits for the method. Also called the *analytical measurement range.*

Primary measurement standard Standard that is designated or widely acknowledged as having the highest metrological qualities and whose value is accepted without reference to other standards of the same quantity.[40]

Reference material (RM) is a material or substance, one or more properties of which are sufficiently well established to be used for the calibration of a method, or for assigning values to materials.

Quantity The amount of substance (e.g., the concentration of substance).

Random error arises from unpredictable variations of influence quantities. These random effects give rise to variations in repeated observations of the measurand.

Reference measurement procedure Thoroughly investigated measurement procedure shown to yield values having an uncertainty of measurement commensurate with its intended use, especially in assessing the trueness of other measurement procedures for the same quantity and in characterizing reference materials.

Selectivity and/or specificity The degree to which a method responds uniquely to the required analyte.

Systematic error A component of error which, in the course of a number of analyses of the same measurand, remains constant or varies in a predictable way.

Traceability "The property of the result of a measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties."[34] This is achieved by establishing a chain of calibrations leading to primary national or international standards, ideally (for long-term consistency) the Système Internationale (SI) units of measurement.

Uncertainty A parameter associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be attributed to the measurand, or more briefly: *uncertainty* is a parameter characterizing the range of values within which the value of the quantity being measured is expected to lie.

*A listing of terms of relevance in relation to analytical methods is displayed. Many of the definitions originate from Dybkær[21] with statement of original source where relevant (e.g., ISO document number). Others are from the Eurachem/Citac guideline on uncertainty.[23] In some cases, slight modifications have been performed for sake of simplicity.

the market (e.g., SPSS, SAS, Stata, Systat, Statview, and StatGraphics). Among programs of an intermediate size, one may mention GraphPad (www.graphpad.com) and SPSS SigmaStat. Excel (Microsoft) also contains various statistical routines. The general programs may lack procedures of interest to clinical chemists (e.g., the Deming and Passing-Bablok procedures). Among more or less specialized programs for clinical chemistry, one may mention Analyze-it (www.analyze-it.com), MedCalc (www.medcalc.be), EP-evaluator (D. Rhoads Assoc., www.dgrhoads.com), and a program distributed by one of the authors (KL) CBstat (www.cbstat.com).

CHAPTER 15

Clinical Evaluation of Methods

Edward K. Shultz, M.D., M.S.,

and Dominik Aronsky, M.D., Ph.D.

Often it is not clear which procedure offers the best information in a specific setting, which procedure is the most cost effective, or which sequence of procedures offers the most efficient route to the solution of a problem. How does one combine a testing result or testing information with previously obtained information? Addressing these questions, this chapter focuses on how to quantify the diagnostic information content of a test or groups of tests and then on how to compare the results with those of other tests. Finally, the cost effectiveness of a test is discussed in the context of outcomes analysis.

The analytical performance of the methods used for many clinical tests has improved dramatically over the past 4 decades. However, a highly accurate and precise test may provide less clinical information than a different test that is less accurate and less precise. For example, a test for total creatine kinase is often more accurate and precise than one for creatine kinase isoenzymes, yet knowledge of the total enzyme activity is of less value in the diagnosis of cardiac damage. How does one evaluate the information content of a test? What procedure should one use to decide among different tests based on their disease discrimination ability? This chapter discusses these and other nonanalytical aspects of test performance that affect a test's overall medical usefulness.

To demonstrate how the concepts described in this chapter can be practically applied, we present the following example: A urologist questions the performance of the current assay to detect prostatic disease. He suggests replacing the current prostate-specific antigen (PSA) assay with a new one that has a greater ability to detect carcinoma of the prostate. He wishes to use the assay annually on his male patients who are older than 50 years of age to screen for prostatic carcinoma. As can be seen in Table 15-1, it appears that the new assay does offer superior performance in this regard. Of the patients with carcinoma, 88% were detected using the new test (Test A), whereas only 82% were detected using the current test (Test B). When healthy men were tested, 96% were correctly classified as not having prostatic carcinoma using Test A; Test B's performance was slightly better, classifying 99% of the subjects correctly.[15]

SPECTRUM

Before an opinion regarding test superiority can be made, the source of the data in Table 15-1 should be considered. In particular, it is appropriate to examine the populations studied and the criteria used for diagnosis. The *spectrum* concerns the medical characteristics of the patients who are involved in the test evaluation. Important aspects include the duration and severity of the disease state, its specific pathological categorization, and the existence of conditions that may affect test performance. Does the study population contain patients typical of those likely to be tested for the disease in question? If the selection criteria make patients with prostatitis or benign prostatic hypertrophy (BPH) more or less likely in the study population than the population to be tested in routine use, the test's interpretation must be qualified by this information.

In this particular case, the patients with carcinoma were identified (in a study by Chan and associates[15]) as having either symptoms or signs of disease. Advanced disease is associated with increases in the number of symptoms and signs and in PSA values. Thus a greater fraction of those

TABLE 15-1 Correct Prediction of Prostatic Carcinoma by Two Prostate-Specific Antigen Assays

Data from references 11, 18, 24, 33, and 41.

reported in this study would be expected to be over the chosen diagnostic cutoff point than nonsymptomatic individuals undergoing an annual screen. The "normal" subjects (drawn from the same work) were patients without known disease; those with BPH, which is a noncancerous enlargement of the prostate, were intentionally excluded. Because our urologist intends to use the assay on BPH patients, and because BPH is associated with higher PSA values, the percentage quoted in Table 15-1 for predicting the presence of a healthy prostate is inflated.

Problems of spectrum are commonly encountered early on in a test's application. Often, very sick patients with advanced disease are compared with unequivocally normal patients to see if a proposed test has any merit. As more realistic clinical populations are tested, performance typically declines. One would expect to see worse performance than the estimates in Table 15-1 in a screening function. One would see an increase in false-negative results owing to the inclusion of less diseased patients and an increase in false-positive results owing to the presence of BPH in the patients being screened (i.e., in those who are older than 50 years of age).

However, the urologist points out that the problems of spectrum are at least constant for both tests. Although the table estimates are not accurate in his population, the relative difference between Test A and Test B in the study would be expected to extend to other populations. Thus it is still advisable to select Test A.

CLASSIFICATION BIAS

How was the diagnosis of carcinoma or the absence of disease established? This question introduces the concept of *classification bias.* Classification bias occurs when an independent standard is not used to judge the validity of a test. A subtle example that involves both spectrum and classification bias occurs in the well-known study by Light and coworkers[33] of the utility of the ratio of serum lactate dehydrogenase to pleural fluid lactate dehydrogenase. The results appear to document excellent differentiation between effusions and transudates. Unfortunately, when a clinical diagnosis could not be made using the remainder of the clinical information available, the case was excluded from the analysis. For the remaining cases, the test offered excellent discrimination. One would expect that small malignancies, which would be less obvious clinically, would also have a more indeterminate ratio. The lack of a gold standard resulted in an overly optimistic appraisal of the test's ability to discriminate between effusions and transudates. Similarly, assumptions have been made about the existence of disease in nonsymptomatic patients in prostatic disease, because it has been impractical to take biopsies in these individuals. For example, Cooner and associates[17] assumed patients who had negative ultrasound and digital examination results had no prostatic disease. Based on this assumption, they derived estimates of the performance of the PSA assay in detecting disease. Their standard for the establishment of disease absence was the assessment of both biopsy and other test results.

Often, alternative candidates for gold standards exist, and this confounds simple interpretation. For example, when step sections of prostates obtained at autopsy or from patients undergoing radical cystectomy were examined, prostatic carcinoma was found in men at a rate more than 10 times higher than Cooner and associates had estimated.[22,27,29,36,43] The silent fraction of nonsymptomatic control subjects who were called "normal" in Cooner's study clearly were not free of carcinoma. This resulted in a higher estimate of the disease detection capability (sensitivity) of PSA at a specific decision threshold. Other studies have used elevated PSA as a criterion for determining which patients should undergo biopsy. When the test in question is used to determine which patients will have the gold standard test or which ones will be included in the diagnostic set, *test referral bias* occurs. Test referral bias can be shown to erroneously increase the true-positive rate in a study population compared with the clinically relevant population.[46] An estimate of the performance of the assay using autopsy data for an estimate of the frequency of disease expected is found in Table 15-2.

A more subtle issue here is the designation of a true-positive result. Medical professionals have been both frustrated and protected in the past owing to their inability to detect early-stage limited disease; they have been frustrated because earlier detection would often have offered the opportunity to treat disease at a time when a cure is possible, and protected because the temptation to overtreat incidental, clinically insignificant disease did not come into play because of detection limits. This protection is diminishing as

TABLE 15-3 Sensitivity and Specificity of a Test Applied to Healthy and Diseased Populations

	No. of Patients With Positive Test Result	No. of Patients With Negative Test Result	Totals
No. of patients with disease	TP	FN	TP + FN
No. of patients without disease	FP	TN	FP + TN
Totals	TP + FP	FN + TN	TP + FP + TN + FN

TP, True positives (number of diseased patients correctly classified by the test); *FP,* false positives (number of nondiseased patients misclassified by the test); *FN,* false negatives (number of diseased patients misclassified by the test); *TN,* true negatives (number of nondiseased patients correctly classified by the test).
Sensitivity = positivity in disease, expressed as a percent = TP/(TP + FN) × 100
Specificity = absence of a particular disease, expressed as percent = TN/(FP + TN) × 100
Likelihood ratio positive (LR^+) = sensitivity/(1 − specificity)
Likelihood ratio negative (LR^-) = specificity/(1 − sensitivity)
Odds ratio = probability of event/(1 − probability of event)

the sensitivity and specificity of diagnostic tools increase. The desire to detect early disease must now often be tempered by reflection on what is clinically relevant disease.

It would appear that the examination of step sections of patient prostates, although more difficult, might at first seem to be as near an absolute gold standard as possible. However, the great majority of prostatic carcinomas (>99%) are clinically indolent and do not decrease life span or increase morbidity.[24,47] A more reasonable true-positive result should reflect identification of those carcinomas that will progress to cause increased morbidity or mortality if neglected.

In the case of prostatic carcinoma, it has been argued that the size of the carcinoma is the best predictor of morbidity and mortality.[24,47] Minimum tumor sizes from 0.2 to 3 cm^3 have been suggested as worth detecting.[24,47] The Hybritech PSA assay uses 4 μg/L as its cutoff. This can be shown to correspond to an average prostatic carcinoma volume, if present, of approximately 1.3 cm^3.[14,48] A tumor of this size would serve as a reasonable cutoff for a gold standard,[56] but it is difficult to size a tumor before complete prostate removal. Using the biopsy as a gold standard is also problematical. Biopsy will detect clinically insignificant disease by chance, but will miss large tumors owing to sampling error. Yet, by its nature, the sampling error of the biopsy is weighted in favor of ignoring small tumors and of detecting large ones. In addition, the number of cancers detected using the biopsy in screening programs is similar to the number of tumors larger than 1.3 cm^3 that were expected. Hence, biopsy is a reasonable substitute for PSA assay. It is adopted as the gold standard for the remainder of this analysis.

Reviewing Table 15-1 after consideration of spectrum and classification bias indicates considerable error in the estimates quoted if they were to be used for annual tests on patient groups consisting largely of BPH patients. A better estimate comes from the data of Chan and colleagues from a comparison of patients with BPH and patients with known prostatic carcinoma.[14,15] The number of carcinoma patients correctly predicted is still an overestimate, because this number includes patients with advanced disease; this would not be the case in the annual screening of the example urologist's patients.

TABLE 15-4 Correct Prediction of Prostatic Carcinoma and Benign Prostatic Hyperplasia (BPH)

Test	Carcinoma (%)	BPH (%)
A, New test	78	58
B, Old test	50	92

SENSITIVITY AND SPECIFICITY

The urologist in the example has assumed that using the test that detects a higher fraction of those with carcinoma is preferable. The *sensitivity* of an assay is the fraction of those with a specified disease that the assay correctly predicts. The *specificity* is the fraction of those without the disease that the assay correctly predicts. Pertinent definitions and formulas for computing sensitivity and specificity are found in Table 15-3. Both sensitivity and specificity are desirable characteristics for a test, but one is typically preferred over the other in different clinical situations.

The data in Table 15-1 have both spectrum problems and bias. The more accurate Table 15-4 can be used to make a decision. However, an illusion has been created here, as is apparent in Figure 15-1. This figure is a dot plot of the performance of a single assay for PSA on patients with BPH and on patients with established carcinoma of the prostate (stages A-D). Note the two dashed lines crossing the graphs that represent diagnostic cutoffs. In fact, Tests A and B in Table 15-4 are not two different assays but rather two decision cutoffs that are applied to the same assay. By moving the decision level to a lower value, the sensitivity has been

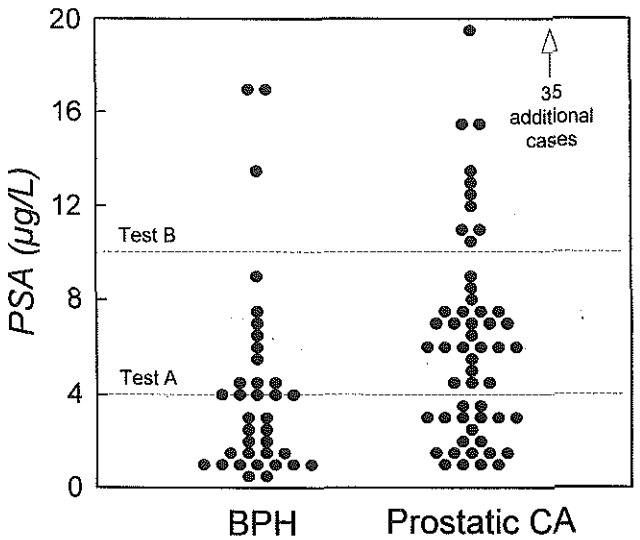

Figure 15-1 Prostate-specific antigen (PSA) levels for patients with benign prostatic hyperplasia (BPH) and known prostatic carcinoma (CA) are shown with two decision-level cutoffs. Tests A and B in Table 15-4 were actually the same test with two different cutoffs.

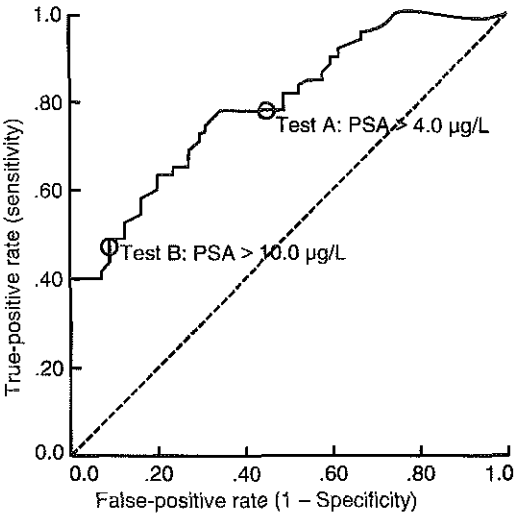

Figure 15-2 Receiver operating characteristic curve of prostate-specific antigen (PSA). Each point on the curves represents a different decision level. The sensitivity (true-positive rate) and 1—the specificity (false-positive rate) can be read for Tests A and B. The true-positive and false-positive rates are demonstrated using 4 and 10 µg/L as decision thresholds.

increased but at the cost of a decrease in specificity. Thus increased true-positive detection was traded for an increase in the number of false-positive results. This tradeoff is not unique to this assay. It occurs in every test performed in medicine. Although it is not often appreciated, it affects the opinions of surgical pathologists and radiologists along with the care provider who performs a physical examination as much as it affects the interpretation of quantitative laboratory results.

RECEIVER OPERATING CHARACTERISTIC CURVES[57]

The dot plot answers quantitative performance questions in only a limited way. One cannot easily estimate sensitivity and specificity for various decision cutoffs using the plot. A graphical technique for displaying the same information called a *receiver operating characteristic* (ROC) curve began to be used during World War II. It was used to examine the sensitivity and specificity associated with the radar detection of enemy aircraft. An ROC curve is generated by plotting sensitivity (y-axis) versus 1 – specificity (x-axis).

For the case at hand, Figure 15-2 shows the ROC curve for PSA using Chan's data.[14] The x-axis plots the fraction of nondiseased patients who were erroneously categorized as positive for a specific decision threshold. This false-positive rate is mathematically the same as 1 – specificity. The y-axis plots the true-positive rate (the sensitivity). A "hidden" third axis is contained in the curve itself: the curve is drawn through points that represent different decision cutoff levels. The whole curve is a graphical display of the performance of the test.

The two Tests A and B from Table 15-4 are displayed as two decision points on the ROC curve. The dotted line extending from the lower left to the upper right represents a test with no discrimination. A curve that is "above" the diagonal line describes performance that is better than random guessing. A curve that extends from the lower left to the upper left and then to the upper right is a perfect test. The area under the curve describes the test's overall performance, although usually we are interested only in the performance in a specific region of the curve.[8] The strength of the ROC graph lies in its provision of a meaningful comparison of different tests. The use in the medical literature of 2 × 2 tables (e.g., Tables 15-1, 15-2, and 15-4) to establish the sensitivity and specificity of a test is a common source of the logical error encouraged in the previous paragraphs. When the initial publication of an assay presents a cutoff for analysis purposes, the assay is often categorized as sensitive or specific based on this cutoff. Yet, as can be seen in the ROC curve, every assay can be as sensitive as desired at some cutoff and as specific as desired at another cutoff.

When comparing two procedures, confusion is avoided by using the ROC curves instead of accepting statements such as "Test A is more sensitive, but Test B is more specific." For example, the usefulness of the prostatic acid phosphatase assay has been compared for years with that of the PSA assay for diagnostic and follow-up purposes. Various claims have been made regarding the relative sensitivity and specificity of the two assays.[18,44]

Figure 15-3 compares the performance of a thymolphthalein acid phosphatase assay with that of the PSA assay for discrimination between BPH and prostatic carcinoma stages A through D. Although each has been claimed to be

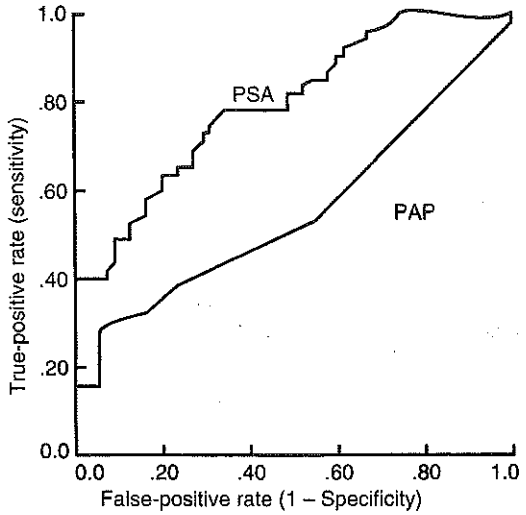

Figure 15-3 Receiver operating characteristic curves of prostatic acid phosphatase (PAP) and prostate-specific antigen (PSA) assays for patients with benign prostatic hyperplasia and prostatic carcinoma. Because the PSA assay curve is above the PAP assay curve at all points, the PSA assay is the better assay for the patients tested.

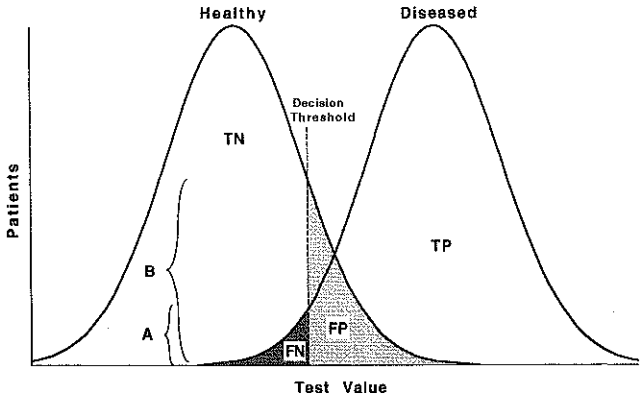

Figure 15-4 Simulated distributions of healthy and diseased populations. Note that the ratio of diseased patients to healthy patients, A to B, is less than 1 and very different at the point of decision (the likelihood ratio) from the ratio of TP to FP, which is much greater than 1. *TP*, True positives; *TN*, true negatives; *FP*, false positives; *FN*, false negatives.

"more sensitive but less specific" than the other by various authors, it is clear from the ROC curves that the authors were choosing different points on the two curves. No matter what level of sensitivity is chosen, the PSA assay offers greater specificity than the acid phosphatase at the same level of sensitivity. This does not mean one should conclude that the PSA assay is always superior. It indicates that for the spectrum of patients used in the assays, the PSA assay offers superior performance compared with that of prostatic acid phosphatase. However, there may be subpopulations in the group tested in which the acid phosphatase assay provides information that the PSA assay misses.

It has been advocated that the area under the ROC curve is a relative measure of a test's performance. A Wilcoxon statistic (or equivalently the Mann-Whitney U-Test) statistically determines which ROC curve has more area under it. Less computationally intensive alternatives, which are no longer necessary, have been described.[8] These methods are particularly helpful when the curves do not intersect. When the ROC curves of two laboratory tests for the same disease intersect, they may offer quite different performances even though the areas under their curves are identical. The performance depends on the region of the curve (i.e., high sensitivity versus high specificity) chosen. Details on how to compare statistically individual points on two curves have been developed elsewhere.[8]

INTERPRETING A TEST

Although the ROC curve improves our capability to judge a test's performance, a result should not be interpreted in isolation. The laboratory scientist must take into account the clinical setting before rendering a specific interpretation. For example, an elevated PSA level in a 35-year-old is not interpreted in the same way as in a 70-year-old because the rate of occurrence of prostatic cancer in 35-year-olds is much lower than in older men.[37] The interpretation is tempered by a knowledge of the prevalence of the disease. The *prevalence* is defined as the frequency of disease in the population examined.[55] For example, using step sectioning of prostate tissue from a random sample of men older than 50 years of age, at least a 25% probability of histological carcinoma can be expected (most of the carcinomas identified will never become clinically important, but they are carcinomas nevertheless).[27,43] Several useful techniques can be applied to combine the prevalence and other previously obtained information with the results of a procedure.

Odds Ratio

The *odds ratio* is defined as the probability of the presence of a specific disease divided by the probability of its absence. The odds ratio reflects the prevalence of the disease in a population. For example, the probability of the occurrence of a 1.3-cm^3 carcinoma in a 75-year-old man is about 8%. The odds ratio of finding histological carcinoma greater than 1.3 cm^3 in size after sectioning the prostate from the autopsy specimen of a man older than 70 years is thus $0.08/(1-0.08)$, or 1:11.5. Findings from a digital rectal examination, from transrectal ultrasonography, or from both are other data that affect the previous probability of the presence of prostatic disease.

Likelihood Ratio

The *likelihood ratio* is the probability of the occurrence of a specific result (given that the disease is present) divided by the probability of the same result if the disease were absent (i.e., sensitivity/[1 – specificity]). For a given result, this corresponds to the ratio of the heights A and B of the two curves at the decision point in Figure 15-4.

Note that the areas under each curve in Figure 15-4 are the same. The likelihood ratio does not take disease prevalence or any other prior information into account. To arrive at a realistic probability, one must adjust for the best estimate of the probability of disease before obtaining the test result. Bayes' theorem provides a method for combining the prior probability information.

Bayes' Theorem

Bayes' theorem provides a method to calculate the probability of a disease after the addition of new information to previously obtained information. These formulas can be incorporated into computer spreadsheets and other computer aids to help in the estimation of updated probabilities. One method, which can be performed without a computer, involves using the odds ratio version of Bayes' theorem. The odds ratio of the occurrence of a disease is calculated before the test result is known; this information is then combined with the results of the test in the form of a likelihood ratio. The final result is again in the form of an odds ratio; this can be converted into a probability, if desired. The advantages of this method are that it is relatively easily memorized and that it requires little mathematical calculation. The odds ratio is useful when it is combined with the likelihood ratio in a more memorable form of Bayes' theorem:

$$\text{Odds ratio after} = \text{Odds ratio before} \times \text{Likelihood ratio}$$

Consider interpretation of a slightly elevated PSA (4.0 to 10.0 μg/L) PSA in BPH. A urologist follows with a transrectal ultrasound examination, which he interprets as giving a positive result. The urologist has performed biopsies on numerous patients similar to this patient and has had many negative results. The urologist finds this perplexing, because both screening tests produced positive results. He or she then requests an estimate of the probability of disease in this patient.

Step 1. *Calculate the odds ratio that carcinoma is present before performing the ultrasound.* Given a PSA of 4.0 to 10.0 μg/L, there is an estimated probability of 12% in a BPH population with biopsy-verifiable disease; thus the probability of no disease is (1 − 0.12) = 0.88. The odds ratio therefore is 0.12/0.88 = 0.14.

Step 2. *Calculate the likelihood ratio of the new information (findings of the transrectal ultrasound).* Screening studies on urology patients report sensitivities of approximately 92% and specificities that range from 30% to 70% (average 50%) for transrectal ultrasound.[13,17,41] The likelihood ratio positive is the sensitivity divided by (1 − specificity), or 0.92/0.50 = 1.8.

Step 3. *Calculate the odds ratio after incorporation of the new information.* The revised odds ratio estimate (the product of Steps 1 and 2) is 0.25.

Step 4. *Convert the odds ratio back into probabilities.* The probability equals the odds ratio divided by (1 + odds ratio), or 0.25/1.25 = 0.2.

Although both tests were positive, the probability of a positive biopsy result is only 20%. If the ultrasound findings had been negative, we would use the inverse of the odds ratio coupled with the likelihood ratio negative. The odds ratio of no disease after the PSA assay, (0.88/0.12) = 7.3, multiplied by the likelihood ratio negative (true-negative rate/false-negative rate = specificity/(1 − sensitivity) = 0.5/0.08 = 6.25) is 43. Converting to probabilities yields 43/(43 + 1) = 98% probability of no disease.

Limitations of Bayes' Theorem

Although Bayes' theorem is widely recommended as an aid to refine the probabilistic estimates of disease, it rests on the assumption of *test independence,* which is often not present. As an extreme example of the possible errors that can occur when nonindependent tests are used, consider testing the PSA level of a BPH patient on 3 consecutive days. Each day, the PSA value is greater than the 4 μg/L cutoff. The likelihood ratio positive of a value greater than 4 μg/L is equal to the sensitivity divided by (1 − specificity), or 0.78/(1 − 0.58) = 1.9. Using the odds ratio form of Bayes' theorem, we would multiply the prior odds (assume 10:90) by the likelihood ratio to obtain the odds after of 0.2, or a probability of 17% after the first test. The odds are $1.9 \times 0.2 = 0.38$ after the second test, and finally 0.72 after the third test. This gives a 42% probability of disease. Very little new information has been provided by the second and third tests, yet the probability of disease has apparently increased from 17% to 42%. A less obvious and less extreme example would result from the combination of the prostatic acid phosphatase results with the PSA results. Although this combination does provide some new information, an acid phosphatase result is related to the amount of prostatic tissue, much as a PSA result is. In contrast, the ultrasound examination is a different approach to the diagnosis, and the information it yields should be more independent of the PSA assay than information yielded by the acid phosphatase results. The lack of test independence is also a problem when using computerized diagnostic programs that employ a Bayesian approach. The amount of independence among different tests for various diseases must often be estimated and tried using a set of test cases. Techniques are being developed to reduce this problem.

Judging independence is difficult without collecting a large set of clinical data and examining them mathematically. A useful approach is to think about the incorrect results given by each test. If both tests tend to yield incorrect results for the same patients, then the tests are not independent, and thus Bayes' theorem cannot be applied to the combination of their results to correctly estimate the probability of disease. For example, the presence of prostatitis or BPH will result in a large number of false-positive results for both PSA and prostatic acid phosphatase assays. Although the tests are not measuring the same analyte and do provide some independent information, combining their results using Bayes' theorem is not appropriate. On the other hand, if the tests

seem intuitively to be independent, then the errors made by assuming independence are not likely to be great.

One should note that test independence is important for accurate probability estimation, but not necessarily for classification. In classification, one has to determine only which disease is the more likely, not its exact probability. Studies have shown that using Bayes' estimation gives quite good diagnostic accuracy even when the tests are not independent. Tests with correlations of up to 0.7 can still be used together to give an idea of the most likely disease.

Combination Testing

Panels of tests are commonly used to increase sensitivity and specificity or when used sequentially to decrease costs. For the practicing laboratorian, the value of panels is limited by the sparse literature on the performance of combinations of tests. The same issue of test independence addressed in the previous section makes it difficult to calculate the performance of panels of tests. In addition, the use of multiple tests can increase the probability of the occurrence of false-positive or false-negative results, depending on how the tests are combined.

Because most reference intervals exclude a fraction of those patients without disease, there is an expected false-positive rate. As multiple tests are added to panels, the probability of false-positive results increases. Efforts to establish multivariate reference intervals that correct for multiple tests and their interrelationships have been made, but the concept has not found widespread acceptance. Although the concept is mathematically quite reasonable, those who have investigated the utility of multivariate reference intervals believe that more work needs to be done before they will be useful.

The gain in test performance to be achieved from combining test results may be illusory. As demonstrated by Table 15-4, by the dot plot in Figure 15-1, and by the ROC curve in Figure 15-2, sensitivity can usually be increased at the expense of decreased specificity. This does not guarantee that the individual test, if the decision threshold were modified to improve sensitivity, would not have comparable performance. For example, consider the data of Chan and associates[14,15] for PSA and prostatic acid phosphatase values in patients with BPH and in those with prostatic disease. Although combining the two individual tests does improve sensitivity, there is a decrease in specificity. Note that using a lower decision threshold for the PSA assay gives comparable sensitivity with improved specificity over the combination. Two observations are important. First, tables can be as misleading for combinations of tests as they can be for single tests. For example, if only the first three rows of Table 15-5 were published, one might conclude that the combination of the two tests offered superior sensitivity. Second, although in this case the two tests do not offer performance that is comparable with that of the single test, in many cases they do. Although it might be assumed that using a single test is to be preferred given equal performance, it is not always the most cost-effective approach. In this example, the prostatic acid phosphatase assay costs less than the PSA assay. If the combination in row three of Table 15-5 offered performance comparable with that of the PSA assay alone, then using the acid phosphatase assay to exclude some patients and subsequently performing PSA assays on patients with higher PSA values may well be the more economical approach.

TABLE 15-5 Performance of Different Test Combinations in Prediction of Prostatic Carcinoma

Test Combination	Sensitivity (%)	Specificity (%)
PSA > 4 μg/L	78	58
PAP > 0.6 U/L	77	25
PSA > 4 μg/L or PAP > 0.6 U/L	92	19
PSA > 1.5 μg/L	91	36

PSA, Prostate-specific antigen; *PAP,* prostatic acid phosphatase.

A widely held belief[54] is that one should test first with a sensitive test and then follow up the occurrence of positive results with a specific test for best performance. The logic is that if the first test determines which patients are to undergo a second test, then the first test should be the more sensitive of the two to ensure that the disease has not been missed. Somewhat surprisingly, even when the first test determines which patients will undergo a second test, the order in which the tests are performed does not affect the combination of sensitivity and specificity. However, it does affect the overall cost. In the following examples, two hypothetical tests that are independent are used sequentially. It is assumed that fixed decision limits are used for the two tests and that the two tests cost the same. Although the tests are hypothetical, the principles are generally applicable to other sequential testing situations.

Example 1. Often care can be optimized if it can be confirmed that a disease is not present. In this case, if screening Test A yields a positive result, it will be followed by Test B; otherwise, testing stops. If Test B yields a positive result, then the overall interpretation is a positive result. Because A *and* B are necessary for the diagnosis, the specificity is improved; however, the sensitivity decreases compared with the use of Test A alone. As shown in Table 15-6, the average cost of the combination varies with the disease prevalence; however, note that performance of the more *specific* test first results in lower expected costs. This lower cost would be accentuated if the second test were to cost more than the first.

The net effect of the use of the test combination compared with the use of Test A alone has been to decrease our false-positive rate fivefold while decreasing the true-positive rate by 0.8%. Whether this tradeoff is desirable

TABLE 15-6 Combination Test Performance Maximizing Specificity*

	Sensitivity (%)	Specificity (%)	Cost
Test A	80	99	$100
Test B	99	80	$100
A followed by B	79.2	99.8	
Prevalence = 0.2			$117
Prevalence = 0.8			$164
B followed by A	79.2	99.8	
Prevalence = 0.2			$136
Prevalence = 0.8			$183

*Results of Test A *and* Test B must be positive to make a positive diagnosis.

TABLE 15-7 Combination Test Performance Maximizing Sensitivity*

	Sensitivity (%)	Specificity (%)	Cost
Test A	80	99	$100
Test B	99	80	$100
A followed by B	99.8	79.2	
Prevalence = 0.2			$183
Prevalence = 0.8			$136
B followed by A	99.8	79.2	
Prevalence = 0.2			$164
Prevalence = 0.8			$117

*Results of Test A *or* Test B must be positive to make a positive diagnosis.

depends on the implications of missing a diagnosis versus generating false-positive results.

Example 2. Diagnosing a curable disease that has a low-cost therapy often increases the relative worth of sensitivity over specificity. If a first test result is negative, a second test might still be performed to maximize sensitivity. Either of two tests that yields a positive result would be interpreted as a positive finding overall. This is more typically the result of tests that are done simultaneously, but also occurs in sequential testing. In Table 15-7, a negative result on the first test is followed by performance of the second test; otherwise, testing stops. If the result of the second test is negative, then the overall interpretation is negative. The cost of performing tests sequentially with this rule varies with prevalence, as seen in Table 15-7.

Using this rule, the combination sensitivity increases as the specificity decreases. Note that the strategy of using the test with the *lower* specificity first results in lower average cost.

Following the strategy outlined in Table 15-6, the first test's specificity determines the cost of sequential testing. When the strategy is to confirm all the negative results of the first test (see Table 15-7), the first test should be the more sensitive so as to minimize costs. As demonstrated in the two examples presented earlier, the decision rule used preferentially trades off sensitivity at the expense of specificity, or vice versa. Although independent tests have been used in these examples, the conclusions are the same for dependent tests. It should be remembered that it is the interpretive rule and the two tests that determine the overall panel performance and costs; the order of testing does not affect performance but can dramatically affect costs.

Multivariate Data Analysis

Diagnosis using computer-generated probabilities from results of multiple laboratory tests has not received wide use. Use has been limited over time to variation of the same analyte, or simple ratios or combinations of two to five variables, as seen with cardiac enzymes or fetal maturity tests. However, this should change dramatically in the coming years as more computer-based support for diagnosis becomes an expectation. At the far end of the multivariable diagnostic spectrum lie mass-throughput molecular biological assaying techniques (e.g., array technologies,[52] mass spectrometry,[16,34] and serial analysis of gene expression [SAGE[40]]), which provide the ability to rapidly and inexpensively measure gene expression levels, presence of polymorphisms, number of copies of genes, and protein concentrations of thousands of genes and proteins *with a single assay* per patient. These molecular profiling techniques can be used with samples obtained from biopsies or from the patient's serum or other biological fluids, and have opened several possibilities for improved tests for diagnosis and for prognosis of clinical outcome, alone or as a response to treatment.

Techniques for combining multiple tests for diagnostic purposes focus on (1) selecting the best subset of all available diagnostic variables, (2) transforming the variables to facilitate separation between diseases and nondiseases, and (3) selecting the best boundaries around the resultant groupings for optimal categorization. One or more of these techniques may be used. As statistical aids become simpler to use, there is less art and more automated performance of these tasks. However, as with all tools, lack of knowledge of the strengths and limitations of the tools can lead to clinically significant errors.

For 2 to 25 variables, methods such as Fisher's discriminant analysis, quadratic discriminant analysis, and neural networks serve to effectively determine diagnostic combinations.[2] Although they are limited to two variables for clarity, the graphs in Figures 15-5, 15-6, and 15-7 show these different approaches. In Figure 15-5, imagine sitting on the *x*-axis beneath the clouds of diseased and nondiseased above you and trying to pick the best spot for a decision point for Test 1. The curves there show the density of the points above you, and that any point chosen will have a significant tradeoff between false positive and false negatives. An identical

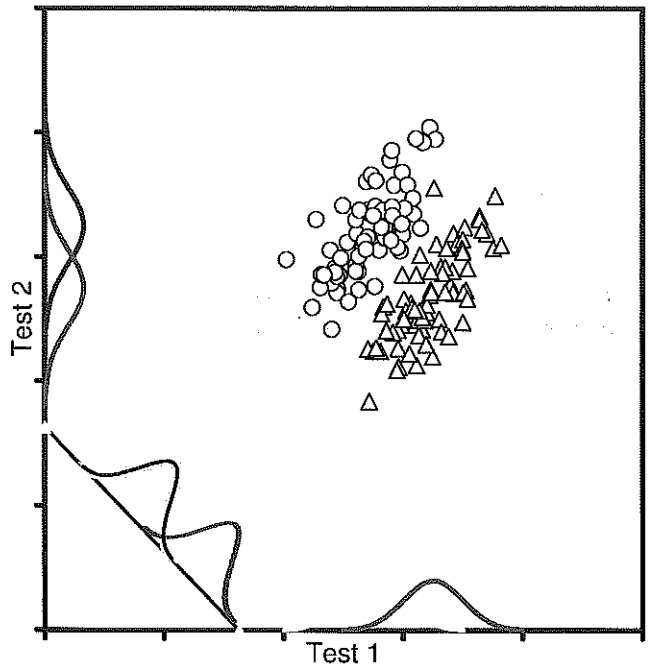

Figure 15-5 Fisher's linear discriminant analysis determines the line, plane, or hyperplane that best separates two populations, based on their mean values and the variance. In the graph, a line bisecting the two curves in the lower left corner provides this "best" discriminator.

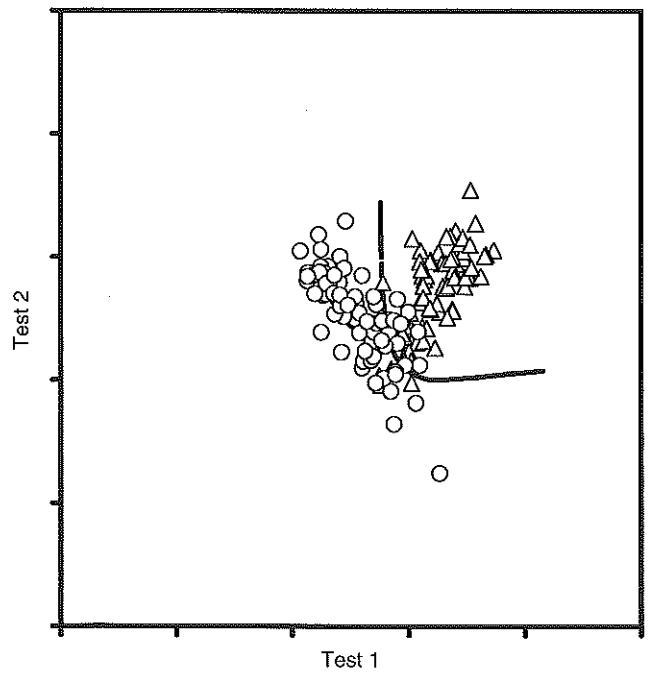

Figure 15-6 Quadratic discriminant analysis removes the constraint of a straight and/or flat plane and allows more molding of the decision boundary than is possible with linear discriminant analysis.

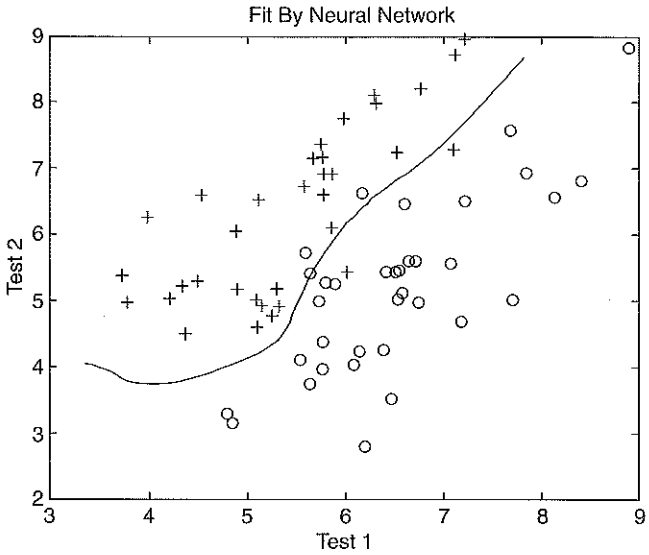

Figure 15-7 Neural networks provide ultimate freedom of discrimination, with the additional danger of "overfitting" a solution. The curved line separating the two populations for this specific set of data may not work well in a subsequent sample since it is custom molded to separate this test set.

situation is true for Test 2, found on the *y*-axis. In Figure 15-5 we see that Fisher's discriminant analysis is seeking to find a viewing point that "best" separates the diseased and nondiseased. "Best" is defined in this test by finding the location where the difference between the means of the two groups is maximized while the apparent clustering (variance) of the values is minimized. The line found in the bottom left corner provides this viewing point. Here the density curves do not overlap significantly, and we can draw a line at right angles to our viewing point that will optimally separate the two groups of points. When more than two variables are involved, the resultant line becomes a plane (three variables) or hyperplane (more than three).

Fisher's linear discriminant works well when the two sets of data have roughly the same shape, but that is the exception rather than the common case. Where the shapes and orientation are different, quadratic discriminant analysis is preferred. As seen in Figure 15-6, we can provide much better separation using a curved line than we would have been able to with a straight line. You could continue using more and more curves in your lines, or more and more complex transformations. Perhaps the most flexible decision boundaries are derived from neural networks, with a possible solution shown in Figure 15-7. So why not always use neural networks if they're so flexible? The result is shown in Figure 15-8, where another sample from a different set of patients has been classified using the Figure 15-7 decision boundaries. This is an example of "overfitting," where we've derived a solution so specifically tailored to a specific set of data that merely resampling the same test from another set of patients decreases the diagnostic performance observed.

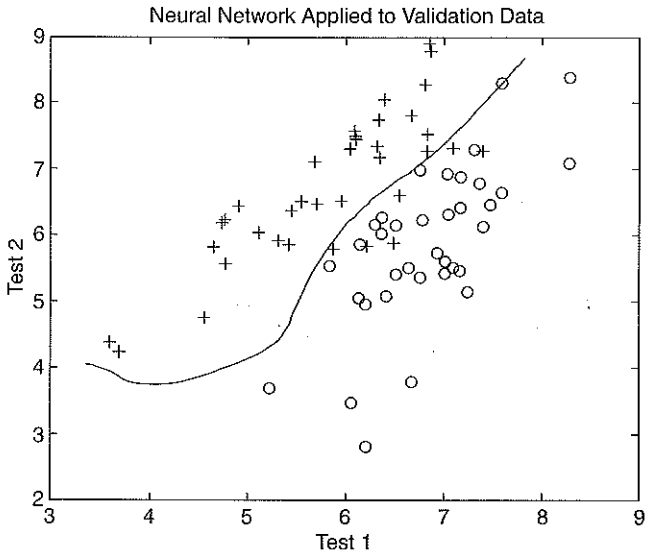

Figure 15-8 The decision boundary derived using a neural net, fit from different data in Figure 15-7, no longer provides optimal separation, although in this case the separation by chance is still good.

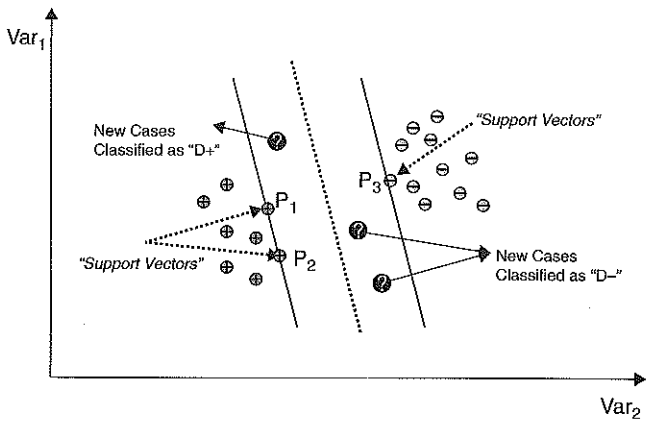

Figure 15-9 A support vector machine (SVM). The patients in the training data are represented by encircled plus and minus signs, while example patients that we have not seen before are represented by encircled question marks. The SVM classifier in this example is the set of the two parallel lines that go through patients P_1, P_2, and P_3, respectively. These two lines specify the "classification margin." Patients P_1, P_2, and P_3 are the "support vectors." Unseen cases are classified according to whether they are closer to the line defined by the disease-positive support vectors P_1, P_3, or to the line parallel to the previous line and the disease-negative support vector P_3.

General procedures for avoiding this are discussed later in the chapter.

Moving from dozens of variables to the thousands of variables found in genomic or proteomic analysis represents a different type of challenge. At least in the current, exploratory stage of examining the diagnostic utility of these profiles, the ratio of *samples to variables* is very small as compared with evaluations of individual tests and traditional panels. In particular, the samples-to-variables ratio is too small to use traditional statistical models (e.g., logistic regression and Fisher's discriminant analysis), because these methods require several patients per estimated model parameter (typically 2 to 10) to function satisfactorily. Genomic and proteomic analyses have a large number of simultaneous variables—in the tens of thousands. In contrast, available data sets of the present and foreseeable future have at most a few hundred patient samples, as is true for most new diagnostic tests. This dilemma is known as "curse of dimensionality" and plagues traditional statistical techniques.

Data Analysis Methods for Very Large Numbers of Variables

Newer data analysis methods overcome the difficulties that small sample-to-variables ratios create for traditional statistical methods. These new methods fall into two major categories: (1) support-vector classification and regression methods, and (2) feature selection and construction techniques. The former are effectively determined by only a small portion of the training data (sample), while the latter select only a small subset of variables such that the available sample is enough for traditional and newer classification techniques.

Support Vector Machines (SVMs)

As with Fisher's linear discriminant analysis, SVMs are classifiers that search for hyperplanes that separate between data points in the data set.[23,42] The separation seeks to maximize the distance between selected (boundary) data points (called the "support vectors") belonging to the different classes (e.g., diseases). Furthermore, nonlinearly separable data are transformed by projection to a higher-dimensional space in which separating hyperplanes can be found. The transformation is achieved through the use of functions ("kernels") such that optimization can be achieved by using only dot products of the original data. Empirical evidence verifies that SVMs are in general very robust to a low sample-to-feature ratio.[12,19,20,26] An intuitive explanation of how SVMs operate and why they have sample requirements much smaller than traditional statistical methods follows.

Consider the example task of classifying patients as having a disease ("D+") or not ("D–") on the basis of real-valued predictive variables *Var1* and *Var2*. Such variables might be for instance gene expression values or protein concentration. For simplicity, the example is in two dimensions but in practice thousands of such dimensions (variables) are used, as discussed earlier in this chapter. Figure 15-9 shows an SVM classifier for this example. First, note that patients in the training data are represented by encircled plus and minus signs, whereas example patients not classified previously are represented by question marks in circles. The SVM classifier in this example is the set of the two parallel lines that go through patients P_1, P_2, and P_3, respectively. These

two lines specify the "classification margin." Patients P_1, P_2, and P_3 are the "support vectors" in this example. Unseen cases are classified according to whether they are closer to the line defined by the disease-positive support vectors P_1, P_3, or to the line parallel to the previous line and the disease-negative support vector P_3. A key observation is that the SVM classifier is *fully defined by its support vectors*. In other words, all remaining training cases are not used for classification once support vectors have been identified by the learning algorithm. It follows that since the total number of support vectors is at most the number of available data (i.e., patients), *the available data are always sufficient to fully specify an SVM model.* In contrast, in classical statistical models we do not seek only a means to correctly classify the data but also an estimate of the process that generates our data (the so-called "generative model"); as a result in a classical regression framework we may not have enough data to estimate a model unless the number of training cases is at least as large as the number of free parameters in our model (and in practice the number of such parameters is at least an order of magnitude larger than the number of predictor variables).
